

VOLUME 1

A microscopic image of numerous rod-shaped bacteria, likely Bacillus subtilis, arranged in various orientations. The bacteria are light blue and have a textured, slightly wrinkled surface. They are set against a dark blue background.

EDITOR-IN-CHIEF

Thomas (Tom) Schmidt is a microbial physiologist and ecologist who studies diverse microbes and microbial communities. Tom received a PhD from The Ohio State University and conducted postdoctoral research at Scripps Institute of Oceanography and Indiana University. He spent much of his career studying the ecology of microbes in soil that are responsible for the exchange of greenhouse gases with the atmosphere. More recently, he joined the University of Michigan and focused his research on the human microbiome. His joint appointment in the Departments of Internal Medicine and Ecology & Evolutionary Biology reflects his expertise in applying ecological and evolutionary principles to understand the functioning of complex microbial communities.

Tom is a fellow of the American Academy for Microbiology and was director of the Marine Biological Laboratory's Microbial Diversity Course in Woods Hole. Through that course and in his laboratory, he has helped numerous scientists incorporate molecular approaches into traditional strategies for studying the microbial world. He currently teaches a university course that merges his research and teaching goals by engaging students in a coordinated study of the effects of diet on the gut microbiome, and he directs a graduate program that combines laboratory sciences and modeling. Tom was a section editor for previous editions of the *Encyclopedia of Microbiology* and was delighted to assume the role as editor-in-chief to help bring the microbial world to an expanding audience.

EDITORIAL BOARD

Bianca Brahamsha is a research microbiologist at Scripps Institution of Oceanography at the University of California, San Diego. She was a biology and history major at Goucher College, earned her PhD in microbiology at Cornell University, and carried out postdoctoral work in molecular genetics as an American Cancer Society fellow at the University of Chicago. Her research interests have centered on bacterial motility, the genetics and physiology of marine cyanobacteria, and on the interactions between cyanobacteria and their eukaryotic predators.

James (Jim) Brown was born in Atlanta, Georgia, and lived in Dade City (Florida), Bloomington (Indiana), Lima (Peru), and Muncie (Indiana) while growing up. From the beginning, he had an intense interest in nature, including anything found in the woods, rivers, beach or ocean that were always nearby.

Jim attended Ball State University beginning in 1976. A single lecture on microbial diversity in a general microbiology class, followed by the announcement of the discovery of the Archaea (George Fox and Carl Woese, 1977), sparked his lasting interest in microbiology. This led to undergraduate research examining *Beggiatoa* in a sulfur spring in French Lick, Indiana. After receiving his BS in biology in 1980, he joined the graduate program in microbiology at Miami University, where he worked on plant tissue culture mRNAs with Prof. Ronald Treick. After obtaining an MS degree in 1982, he moved to the MCD Biology Program at The Ohio State University to work on the molecular biology of methanogenic Archaea in the Department of Microbiology with Prof. John Reeve. While there, Jim worked on polyadenylation of mRNAs, RNA polymerase, and promoters in Archaea, and received his PhD in 1988. Jim then went to Indiana University for 5 years of postdoctoral work in Prof. Norman Pace's lab on the comparative analysis of the structure of a bacterial ribozyme, RNase P.

In January of 1994, Jim started as an assistant professor in the Department of Microbiology and moved to North Carolina State University. Research in Jim's lab focused on the comparative sequence and biochemical analysis of RNA, and in particular RNase P in Archaea. Students in the Brown lab developed a high-resolution model for the structure of this RNA, how it changed over the diversification of the Archaea, the protein subunits associated with the RNA, and how they contribute to the function of the holoenzyme. Jim developed, teaches, and wrote the textbook for a senior-level undergraduate lab course in microbial diversity. Jim is now Professor Emeritus in the Department of Biological Sciences at NC State University.

Jim has a son and two daughters, and is married to Melanie Lee-Brown, professor of biology and director of Research and Creative Endeavors at Guilford College. For fun, Jim enjoys skin and scuba diving, driving (i.e., working on) his 1968 Lotus Super Seven, and restoring vintage racing bicycles. Jim and Melanie have been renovating an abandoned fishing lodge on North Caicos Island (Turks and Caicos Islands, BWI), which will be reopened soon as a bed and breakfast.

Larry Forney is a university distinguished professor and a member of the American Academy of Microbiology with academic appointments in the Department of Biological Sciences and Bioinformatics and Computational Biology at the University of Idaho. Dr. Forney is an evolutionary ecologist who conducts research on the complex array of factors that influence the function, composition, structure, and temporal dynamics of bacterial communities in a wide array of habitats. In recent years he has largely focused on the community ecology of the human vagina across a woman's lifetime with an eye on understanding how changes in community structure and function affect a woman's risk to bacterial vaginosis, sexually transmitted infections, and pre-term birth, and how host factors shape these communities. His research extends to understanding the mutation-selection processes that govern the occurrence and persistence of genetic diversity of bacterial populations in spatially structured environments such as microbial biofilms and porous media. These studies have shown that spatial structure creates condi-

tions in which mutation frequencies are high and selective sweeps are protracted, which leads to extraordinary within species diversity that increases the resilience of populations to environmental changes.

Robert Haselkorn was the F. L. Pritzker distinguished service professor of molecular genetics and cell biology at the University of Chicago, retiring several years ago. He was an undergraduate at Princeton, a graduate student at Harvard, and a postdoctorate in Cambridge, England. He started his teaching career at Chicago in 1961 in biophysics, extending later to microbiology, biochemistry, and chemistry. His research interests have centered on heterocyst differentiation in nitrogen-fixing cyanobacteria, in bacterial genomics, and in the enzyme acetyl-CoA carboxylase in plants, parasites, and people. He is a member of the National Academy of Sciences, a fellow of the American Academy of Arts and Sciences, and a member of the American Philosophical Society. Among other external activities he was a founder and adviser for 20 years to the International Center for Genetic Engineering and Biotechnology, located in Italy and India. For the past 15 years Haselkorn and his wife Margot have been working on selection and supporting a speaker for the Haselkorn Lecture at the University of Chicago,

an award they have endowed. Many of the Haselkorn Lecturers have been Nobel Prize winners or will be soon.

Jennie C. Hunter-Cevera received her PhD from Rutgers University in 1978 (microbial physiology and biochemistry), an MS in microbial ecology in 1972, and a BS in biology from West Virginia University in 1970. She is the founder of Hunter and Associates, a consulting firm focusing on finding integrative solutions to complex problems involving sustainability in the life sciences arena. From July of 2009 to August 2012, she was the executive vice president of Discovery and Analytical Sciences (DAS), Corporate Development and Government Relations. She has 22 years of experience in the pharmaceutical and biotechnology industries (E. R. Squibb and Sons, Cetus Corporation, GeoBiotics, and Universal Foods). She was the co-founder of The Biotic Network and Blue-Sky Laboratory that contracted with biotechnology and pharmaceutical companies on basic and applied natural product research. Dr. Hunter-Cevera was an

employee for 5 years with the Department of Energy as the head of the Lawrence Berkeley National Laboratory's Center for Environmental Biotechnology. She worked in academia for 10 years as the president of the University of Maryland Biotechnology Institute and 2 years as the Interim Provost of Mount St. Mary's University. She also served as project manager for UC Davis's CIFAR (Center for Industrial Food and Agricultural Research). She has published many papers and chapters, and served as senior editor of the *Journal of Industrial Microbiology and Biotechnology* for 10 years. She is a co-section head of microbiology for Faculty of 1000. She holds 15 patents and specializes in areas of screen design for the discovery of natural compounds in the area of human therapeutics, biodefense, sustainable agriculture, bioremediation, and biocatalysis for industrial processes in the food and clothing industries.

While in Maryland, she served as a member of the Executive Committee for Governor Ehrlich's transition team, his Committee on science, technology, engineering, and maths, and was the Technology Representative for Governor Glendenning on the Southern Governor's Association, and she served on the Technology Economic Development Corporation, TEDCO (Board of Directors for 4 years and was Chair for 2 years). Dr. Hunter-Cevera also served on the Advisory Board for the Maryland Industrial Partnerships, the MDBio's Board of Directors, and the MDBio Foundation for 10 years and on the BioIT Coalition for 5 years. She served as an Entremed Board Member for 10 years and served on the Executive Committee for 2 years. She was a board member for Patients with Power, a software company that designs programs for cancer patients to make the best decisions for their treatments. Jennie also served as acting secretary for Maryland's Higher Education Commission in 2015.

She is a member of several professional societies and has served as president of the Society for Industrial Microbiology, the International Marine Biotechnology Association, and the United States Federation of Culture Collections. Dr. Hunter has served on many national committees and commissions and was Chair of the National Research Council's Committee on Large Scale Production of Biofuels from Algae. She also chaired two other NRC Committees: Standing Committee on DOD's Translational Medicine and the DOE's Genome to Life for Biofuels.

She is the recipient of several awards and honors including Maryland's Top 50 Influential People (2007, 2009) and Maryland's Top 100 Women (2003, 2006, 2009), American Society for Microbiology's Porter Award for distinguished research in microbial systematics and taxonomy, elected as a SIM fellow, a member of the ASM Academy of Microbiology, and an AAAS fellow. She is also a WVU Distinguished Alumni Awardee and Nath lecturer and served as an entrepreneurial coach for the UNC Executive MBA program. She was awarded an Honorary Doctorate from West Virginia University, May 2013, and the Rutgers Cook College Dennis M. Fenton Distinguished Graduate Alumni Award in 2014.

She currently serves on the International Advisory Council for Brazil's Fundação Dom Cabral which is a world-class Brazilian business school that develops strategic thinking skills of executives, entrepreneurs, and public-sector managers. In addition, Jennie served 6 years on the Edison Awards Steering Committee and currently serves on the Edison Awards Advisory Board.

Stanley Maloy is a professor of microbiology and associate vice president for research and innovation at San Diego State University. Stanley's research has focused on bacterial and phage genetics and physiology, evolution of infectious diseases, and development of antimicrobials and vaccines. In addition, he has consulted with large and small companies in multiple sectors, played a role in starting several Biotech companies, and served leadership roles in multiple start-up companies.

Dr. McCormick earned her PhD in microbiology in the topic area of intestinal ecology, and completed postdoctoral training at Harvard Medical School. She remained on the faculty of Harvard Medical School where she was an associate professor of pediatric gastroenterology, and director of research for the Mucosal Immunology and Biology Research Center at Massachusetts General Hospital. In 2008, she joined the University of Massachusetts Medical School where she is professor and vice chair of the Department of Microbiology and Physiological Systems. Dr. McCormick is also the founding executive director of the University of Massachusetts Center for Microbiome Research, which she established in 2014. Dr. McCormick is one of the original pioneers in the field now known as cellular microbiology. Her work provided the first evidence that epithelial cells in response to pathogen contact orchestrate a pro-inflammatory program, which recruits inflammatory cells. Dr. McCormick has since identified new, previously

unidentified and unexpected virulence mechanisms that are key to the inflammatory response, leading to both novel biological principles of host-microbe interactions and therapeutic intervention strategies for the treatment inflammatory bowel disease, and cancer. Her work continues to identify novel ways in which microbes interact with the intestinal epithelium, publishing over 100 original research papers and opinion pieces in this area. Dr. McCormick is an elected fellow of the American Academy of Microbiology, is on the Board of Editors for *Gastroenterology*, and *Gut Microbes*, and serves as a member of four Editorial Review Boards.

Dr. Mobley received his BS degree in biology from Emory University in 1975 and his PhD degree in microbiology and immunology from University of Louisville in 1981. He conducted postdoctoral training in biological chemistry and then bacterial genetics in the Center for Vaccine Development at the University of Maryland School of Medicine. He served on the faculty at the University of Maryland School of Medicine from 1984 until 2004 in the Division of Infectious Diseases (1984–97) and then the Department of Microbiology and Immunology (1997–2004) where he led the graduate program. During that time, he held a joint appointment in the Department of Biochemistry and Molecular Biology and trained graduate students in that program. In 2004, Mobley moved to the University of Michigan to chair the Department of Microbiology and Immunology and was installed as the inaugural Frederick G. Novy Collegiate Professor of Microbiology and Immunology.

Dr. Mobley's research interests focus on the molecular mechanisms of bacterial pathogenesis and on the fundamental basic research that will lay the groundwork for future therapeutics and vaccines. His lab studies virulence mechanisms of uropathogenic *Escherichia coli* and *Proteus mirabilis* that cause uncomplicated and complicated urinary tract infections, respectively, and, in the recent past, *Helicobacter pylori* that causes gastritis and peptic ulcer disease. For *E. coli* and *Proteus mirabilis*, his lab is focused on identifying surface-exposed proteins that are both synthesized by the bacteria during a urinary tract infection and conserved among uropathogenic *E. coli* and *Proteus* strains. Using these conserved antigens, his lab is determining the efficacy of candidate proteins as components of a multivalent subunit vaccine to protect against urinary tract infection.

Dr. Mobley is a fellow of the American Academy of Microbiology and a fellow of the American Association for the Advancement of Science and a member and past president of the Association of Medical School Microbiology & Immunology Chairs. He was the recipient of the inaugural University of Michigan Postdoctoral Association Excellence in Mentorship Award in 2012. He is a member of the editorial review boards of *Infection and Immunity* and *Microbiology Spectrum* and has served as a study section member for the National Institutes of Health. Dr. Mobley was awarded and named a distinguished university professor in 2015. This is the University's most prestigious professorship established to recognize senior faculty with exceptional scholarly achievements, national and international reputations for academic excellence, and superior records of teaching, mentoring, and service.

Dr. Mobley has published 255 peer-reviewed articles which have been cited in the literature over 18,000 times as of June 2019, as well as 49 book chapters and 5 books. He has trained 29 PhD students and 38 postdoctoral fellows, and has delivered 232 invited lectures in 21 countries.

Carlos Pedrós-Alió graduated in biology at the Autonomous University of Barcelona and got his PhD in bacteriology at the University of Wisconsin–Madison. After a postdoctoral stay at the Autonomous University he became an assistant professor of microbiology. He moved to the Marine Sciences Institute (CSIC, Barcelona) in 1989 where he was a research professor since 2000. In 2016 he moved to the National Center for Biotechnology (CSIC, Madrid). Dr. Pedrós-Alió's interest is to understand the ecology of aquatic microorganisms. Around 2005 he started to use genomics as a tool to generate hypotheses that could later be tested experimentally. He also likes to study extreme environments such as hypersaline systems, thermal springs, or polar waters. Another interest is in finding the mechanisms maintaining a large number of rare bacteria in aquatic ecosystems. He is also interested in outreach, relationships between art and science, biology of spirituality, fiction writing, and birding.

PREFACE

As with previous editions of the *Encyclopedia of Microbiology*, the 4th edition takes on the challenge of providing a contemporary overview of microbes—the most abundant and diverse forms of life on Earth. These single-celled organisms were the first life forms to inhabit Earth and they transformed the planet and its atmosphere. They continue to maintain Earth's atmosphere, drive essential processes in terrestrial and aquatic ecosystems, and form intimate relationships with all plants and animals. Microbes can reproduce by doubling every 20 minutes or can remain dormant for many thousands of years. They colonize every known habitat on Earth, accounting for approximately half of the living biomass on our planet. Microbes also cause the most devastating diseases known to humans and are winning the antibiotic war we wage against them. Yet, we cannot live without microbes as symbionts of humans and drivers of Earth's biosphere.

Despite the central roles of microbes, we are only just becoming aware of our limited knowledge of interactions among microbes, other organisms, and the environment. Molecular techniques continue to lead a revolution in our understanding of microbial diversity and function, with the new “big data” sciences of genomics, transcriptomics, proteomics, and metabolomics now being applied to communities of microbes. These techniques provide the ability to identify and study complex communities of microbes in diverse environments including the human gut, forest soil, water-treatment biofilters, and the open ocean.

Given the remarkable physiological and phylogenetic diversity of microbes, their capacity for rapid evolution, and the pivotal role of host-associated and environmental microbiomes, it is difficult, if not impossible, to identify contemporary questions in biology that are not influenced by microbes. It is also increasingly difficult to assemble an encyclopedia that provides comprehensive coverage of the vast universe of microbes. Despite these challenges, we have engaged the expertise of scientists around the globe to provide an exceptional overview of and perspective on the microbial world. This edition of the *Encyclopedia of Microbiology* will help readers develop a framework for understanding microbes and will provide references directing readers to the primary literature that is needed for a more thorough appreciation of specific topics.

We have included a number of articles which provide a historical perspective of microbiology that is focused on disease—one of humanity's earliest acknowledgment of microbes. These help frame more contemporary issues in microbiology that have moved far beyond the relatively small collection of microbes that cause disease. Rather than simply alphabetize topics as in traditional encyclopedias, articles in the 4th edition are also listed under the following themes in a Subject Classification: Historical, Microbial Diversity, Physiology and Genomics, Ecology and Evolution, Pathogenesis and Immunology, and Technological Advances and Applied Microbiology. We hope this helps readers navigate the work more effectively.

On behalf of an insightful and collegial editorial team, I hope that you emerge from your forays into the *Encyclopedia of Microbiology* with some of the awe that we share for the elegance and power of the microbial world.

Thomas M. Schmidt
Editor-in-Chief

INTRODUCTION: MICROBIAL DIVERSITY

It is what we think we know already that often prevents us from learning.

—Claude Bernard

One of the difficult lessons for any professional scientist is that, as much as we know, as good as our tools and questions are, our knowledge is crude and far smaller than we imagined when we were students. Particularly troublesome is that most fundamental aspects of various scientific fields are simply not very well understood. The physicist wonders what, exactly, “time” is, how space is structured, and why the Planck Constant is $6.62607004 \times 10^{-34} \text{ m}^2 \text{ kg/s}$ instead of any other number you might care to choose. Chemists argue about the nature of a covalent bond, or whether or not transition states exist in reality. Biologists are at a loss to describe how life originated, or even what exactly life (in a general sense) actually is. In the most important book of modern times, “On the Origin of Species,” Charles Darwin clearly (but not concisely) deconstructs the idea of the biological “species,” and despite what many of us learned in school, our view of the “species” even for multicellular sexually reproducing creatures remains murky. The modern reader of “On the Origin of Species” might be forgiven for concluding that the reason for this is that it is the actual *biology* of species, and by extension “life,” our origin, etc., rather than our concepts of them, that are fundamentally disordered.

The subject of this section of the Encyclopedia is Microbial Diversity. What does this mean? What is “microbial diversity?”

Let us start with “microbial.” Literally speaking, the term “microbial” means small living things, usually understood to mean life too small to see with the unaided eye. The scientific field of microbiology, however, mostly emerged from our need to solve crucial health dangers created by a tiny fraction of microbes. As a result, “microbiology,” and so “microbes,” refer to Bacteria (and in modern times the Archaea), fungi, a scattering of problematic single-celled or small multicellular eukaryotes, and the physiological systems of the human body that manages our interactions with these creatures. This sells the microbial world very short. For 85% of the history of our planet, life was *entirely* microbial, and it remains *predominantly* microbial. In the words of Stephen J. Gould, “*We live now in the ‘Age of Bacteria.’ Our planet has always been in the ‘Age of Bacteria,’ ever since the first fossils—bacteria, of course—were entombed in rocks more than 3 billion years ago. On any possible, reasonable or fair criterion, bacteria are—and always have been—the dominant forms of life on Earth.*” Another view of this comes from the phylogenetic perspective. If you scrutinize any objective/quantitative “Tree of Life,” based on molecular sequence analysis or any other criterion of choice, you will quickly discover that nonmicrobial life is limited to the tips of a small number of otherwise un-noteworthy branches. Only from our self-centered anthropocentric viewpoint is microbiology distinguishable from biology as a whole.

And what of “diversity?” Living things and their morphology, structure, physiology, ecology, internal mechanisms, behavior, interactions, etc., are far more diverse than most of us have been led to believe. For example, if you think you know how mitosis works, look it up in *Giardia* and be amazed. The notion of what constitutes a “gene” in the kinetoplast of *Trypanosoma* requires you to throw almost everything you think you know about molecular genetics away. Then have a look through the genome of the archaeon *Nanoarchaeum*. These are just the tips of icebergs; these and many more can be found within the chapters that follow. And yet . . . all of this diversity rests over an almost entirely uniform biochemistry that speaks to the shared ancestry of all living things on Earth. How, then, do we assess the “diversity” of living things? Historically, this meant comparing the morphology of different living things; this was the origin of Linnaean taxonomy and, to be fair, is very useful for organisms on the human size scale. More recently molecular phylogenetics has allowed us to more clearly understand how creatures are related, and draw an objective and quantitative graph of these

relationships; the molecular “Tree of Life” is a more useful roadmap of biological diversity. But it is clear that an even more sophisticated view of biological diversity is required, for example to describe how horizontal gene transfer impacts “diversity,” and many of these questions emerge from microbiology. Perhaps the most important fundamental question in microbiology today is “What is a microbial species?” In other words, how do we conceive of a “species” in organisms that do not reproduce sexually? This is not a trivial or parochial question; remember that the concept of biological evolution, and so the foundation of the science of biology, emerged directly from exploration of what a “species” is and how it originates, in plants and animals. But this was over 150 years ago. Broadening our view of microbial diversity, how it is structured and its history and origins, is the key to new and deeper biological insight.

And so, as is usual in science, attempt to answer a simple question that raises many more questions and provides few answers. What is microbial diversity? I dunno, but let us have a look. ...

James Brown

INTRODUCTION: PHYSIOLOGY AND GENOMICS

The first two editions of EOM were edited entirely by Dr. Joshua Lederberg. The third edition was also planned largely by Dr. Lederberg, but he died during that phase, in 2008, and was replaced by Dr. Moselio Schaechter, promoted from the ranks of associate editors. Dr. Thomas Schmidt was also an associate editor for that edition and moved up to editor-in-chief for the fourth edition.

The time that has passed from the first to the fourth edition has seen remarkable advances in understanding the variety of microbes. Complete genome sequences were determined for 18 microbes by October 1998 and published in the second edition in 2000. By 2019, a single company had determined the complete annotated genome sequences of several thousands of microbes. Comparative genomics, including the ancillary “omics,” as well as the application of systems biology to reconstruct metabolic networks, have provided new insights into many aspects of microbial physiology and genetics. The advent of cryo EM and of single particle cryo EM has revolutionized how we understand the structure of cells and macromolecules. For this fourth edition, we were guided by the splendid organization of the third and additional areas in which considerable advances have been made. The fourth edition now includes articles describing additional features of microbiology: cryo-electron microscopy, CRISPR/*cas*, and metabolic systems biology, as examples of completely new methods to study microbes, circadian rhythms as an important aspect of the physiology of at least one group of microbes, and new developments in our understanding of the many ways in which bacteria and archaea move. We have also made use of updates of chapters that were included in the third edition.

Bianca Brahamsha
Robert Haselkorn

INTRODUCTION: ECOLOGY AND EVOLUTION

Evolution

Seven articles deal with different aspects of evolution. Two articles analyze the remains of the past evolution of microbes in the fossil record. Three other look at theories, mechanisms, and experimental procedures. Two more examine specific aspects of the evolution of viruses and of a ciliate. Finally, one article bridges ecology and evolution looking at the emerging field of evolutionary ecology of microbes.

Ecology

The ecology section contains a few general articles about what microbial ecology is about, and the particularities of the ecology of viruses and rare microorganisms.

The remaining articles can be placed in two complementary approaches: habitat oriented or process oriented. In the first approach there is a lot of attention devoted to extreme environments. These environments are usually exclusively microbial and show the capacity of microbes to deal with really difficult conditions. Besides, the relative simplicity of such ecosystems allows somewhat easier manipulations than in “normal” ecosystems. Several of the latter are also examined in articles ranging from the deep ocean to plastics. Special attention is given to animal and plant habitats and how microbes interact with their hosts.

The process-oriented approach shows, on the one hand, adaptive traits of microorganisms such as the ability to live in diluted environments or to use chemotaxis to find the optimal conditions. One promising and novel avenue to study adaptations is the analysis of the genomes of uncultured microorganisms. On the other hand, several articles review processes relevant at the ecosystem level, from feeding strategies such as myxotrophy to element cycles such as methane formation and oxidation and, finally, to the use of models in microbial ecology.

We hope this collection of articles provides an overview of the exciting times that microbial ecology is going through, with many new discoveries appearing every few years, and a fascinating and invisible world to be explored.

Carlos Pedrós-Alió
Larry Forney

INTRODUCTION: PATHOGENESIS AND IMMUNOLOGY

This section of the encyclopedia focuses on the relatively narrow slice of all microbes that infect living hosts and how the hosts combat these microbes using innate and adaptive immunity. In addition, we examine how antimicrobial agents including unique metabolites and even bacteriophages have been enlisted to combat these infections. This section takes a broad look at infectious agents ranging from prions, viroids, and satellites to the more traditional etiologic agents like bacteria, viruses, fungi, and selected parasites. Also addressed are epidemiologic and diagnostic techniques used to identify and track the spread of infectious microbes including the most advanced diagnostic methods used by the clinical microbiology laboratory. A closer look at pathogenic mechanisms includes groups of virulence factors such as adhesins, iron acquisition, exotoxins of bacteria and fungi, and bacterial endotoxin (lipopolysaccharide). Strategies adopted by bacteria and fungi to colonize implanted foreign bodies such as catheters are also discussed. Plus, infections of the gastrointestinal tract, lung, oral cavity, and the skin are examined. In addition to pathogenic microbes, some articles examine the protective effect of the microbiome and commensal organisms. With respect to immunity this section also focuses on the interplay of the host immune system with pathogenic microbes covering evasion immune strategies in humoral and cellular immunity as well as innate immunology and the complement immune system.

Beth McCormick
Harry Mobley

INTRODUCTION: TECHNOLOGICAL ADVANCES AND APPLIED MICROBIOLOGY

This section focuses on the development and refinement of the tools commonly used for both basic and applied microbiology. The articles in this section are written by authors who personally have worked on developing and fine-tuning technology for research in microbiology. Many of the products and processes described have multiple uses in a variety of disciplines such as health, the environment, food and agriculture, and industrial biocatalysis. The advances made in sequencing, protein analysis, and bioinformatics have given microbiologists new insights into old problems. These advances have also enabled the rapid identification of microorganisms in studies of biowarfare, infectious disease, and pollution of our water sources. At the same time the integration of mathematics and physics with biology and chemistry has provided instrumentation that enables a greater depth of analysis than ever before. Never in the history of microbiology have so many technological advances been developed and commercialized for use by scientists. Microbiologists today are equipped with improved “tools” within the toolbox to push the boundaries of not only elucidating the relationship of microbes to humans, plants and animals but also moving basic research much faster from the bench to development of new products and processes that benefit society and the planet. The renaissance of applied microbiology powered by technological advances has been both exciting and promising in all fields of study.

Defining Statement

The phylum *Acidobacteria* is one of the most abundant bacterial phyla in soil, yet little information is available on their physiology, ecological function, and impact on the soil environment. This lack of clarity is mainly due to the low number of cultured *Acidobacteria* representatives and their slow growth *in vitro* under standard laboratory conditions.

Overview

Acidobacteria is a ubiquitous and abundant bacterial phylum in soil, but the factors underlying their ecological advantage in the soil ecosystem remain unclear, as isolation difficulties and slow growth *in vitro* have limited the number of cultured representatives. However, non-culturable approaches, mainly 16S rRNA gene surveys, have revealed that *Acidobacteria* are metabolically diverse and widely distributed. Most *Acidobacteria* are aerobes, but some can grow under reduced oxygen conditions (1%–2% O₂). The diversity and abundance of *Acidobacteria* have been reported in a variety of sites, such as diverse agricultural and contaminated soils, sediments, forest soils, peatland, various water systems, acid mine drainage and surfaces of Palaeolithic caves and catacombs. The few sequenced genomes of *Acidobacteria* indicate a broad substrate range of ABC transporters for nutrient uptake, suggesting an advantage of *Acidobacteria* in complex environments and adaptation to oligotrophic conditions, such as nutrient-limited soil conditions.

Acidobacteria form as much as 50% of the total soil bacterial community based on 16S rRNA gene phylogenetic sequence surveys and compose on average 20% of the total microbial community in soils around the world. Three subdivisions are particularly abundant in soils: class *Acidobacteriia* (former subdivision 1), class *Blastocatellia* (former subdivision 4) and subdivision 6. At present, members of class *Acidobacteriia* are the most readily culturable under laboratory conditions. Together with subdivision 3, *Acidobacteriia* are the most abundant groups in soils.

The existence of the phylum *Acidobacteria* was first recognized in 16S rRNA gene sequence-based studies, which revealed that *Acidobacteria* and *Proteobacteria* were the predominant phyla in diverse soil environments. It was predicted that *Acidobacteria* would be as diverse as the widely studied phylum *Proteobacteria*. Only 4–5 subdivisions were initially described in 1997, a number that increased to 8 subdivisions in 1998 and 11 in 2005. The diversity and phylogeny of *Acidobacteria* currently encompasses 26 known subdivisions (Fig. 1) belonging to seven families: *Acidobacteriaceae*, *Bryobacteraceae* (within class *Acidobacteriia*),

Fig. 1 Dendrogram of *Acidobacteria* subdivisions. The dendrogram was constructed using 16S rRNA gene sequences from the 26 *Acidobacteria* subdivisions downloaded from the RDP 11 and NCBI databases. The sequences were aligned using the tool align.seqs in the software Mothur against Silva database version 132. The software Mega 7 was used to build the dendrogram based on the neighbour-joining method with 1000 bootstraps. The circles represent bootstrap values above 0.75. *Pyrococcus furiosus* was used as an outgroup.

Blastocatellaceae, *Pyrinomonadaceae* (within class *Blastocatellia*), *Acanthopleuribacteraceae*, *Holophagaceae* (within class *Holophagae*) and *Vicinamibacteraceae* (within subdivision 6).

Despite their high abundance in several environments, only 60 *Acidobacteria* species have been described so far (Fig. 2). The first isolate belonging to this phylum was *Acidobacterium capsulatum*, from which the name of the phylum was derived; the genus *Acidobacterium* was first proposed in 1991 for acidophilic, chemoorganotrophic bacteria isolated from an acidic mineral environment. Most *Acidobacteria* isolates belong to two classes: *Acidobacteriia* (39 species) and *Blastocatellia* (13 species), while three species belong to *Holophagae*, three to subdivision 3, two to subdivision 6, one to subdivision 10 and one to subdivision 23. Two *Acidobacteria* isolates belong to *Candidatus* genera: '*Ca. Koribacter*' (*Acidobacteriia*) and '*Ca. Solibacter*' (subdivision 3). In 2018, three new *Candidatus* genera with features of dissimilatory sulphur metabolism were proposed based on metagenome-assembled genomes: '*Ca. Sulfotelmatobacter*', '*Ca. Sulfotelmatomonas*' (Class *Acidobacteriia*) and '*Ca. Sulfopaludibacter*' (subdivision 3).

The genus *Acidobacterium* belongs to the family *Acidobacteriaceae* (class *Acidobacteriia*), which also contains the genera *Edaphobacter*, *Terriglobus*, *Acidicapsa*, *Acidipila*, *Bryocella*, *Granulicella*, *Occallatibacter*, *Telmatobacter*, *Terracidiphilus*, *Silvibacterium* and '*Candidatus Koribacter*'. These bacteria are gram-negative chemoorganotrophs with prevalent capsule formation and variable motility. They are aerobic or facultatively anaerobic and mostly mesophiles, although some are cold adapted. The members of this genus prefer sugars as a source of carbon and energy and are able to degrade complex carbohydrates. Their genomic G+C content varies from 51.7% to 62.1%.

The family *Bryobacteraceae* (subdivision 3) is formed by the genera *Bryobacter*, *Paludibaculum* and '*Candidatus Solibacter*'. These bacteria are chemoheterotrophic, gram-negative, non-spore-forming rods that are aerobes and facultative anaerobes and can use various sugars as growth substrates. In addition, members are mildly acidophilic, mesophilic and psychrotolerant. Their genomic G+C content varies from 55.5% to 61.9%.

The family *Blastocatellaceae* (subdivision 4) contains the genera *Blastocatella*, *Aridibacter*, *Tellurimicrobium* and *Stenotrophobacter*. The members of this family are gram-negative, non-spore-forming, non-capsule-forming bacteria. In addition, these aerobic

Fig. 2 Dendrogram of *Acidobacteria* isolates based on nearly full-length 16S rRNA gene sequences from the RDP 11 and NCBI databases, aligned using the tool align.seqs in the software Mothur against Silva database version 132. The software Mega 7 was used to build the dendrogram based on the neighbour-joining method with 1000 bootstraps. The circles represent bootstrap values above 0.75. The dendrogram includes sequences from the 60 described species, 2 candidate genera and *Pyrococcus furiosus* as an outgroup.

chemoorganotrophs are unable to reduce nitrate or ferment glucose and are slightly acidophilic to neutrophilic mesophiles with a preference for complex proteinaceous growth substrates, although a few complex carbohydrates can be used. Their genomic G+C content ranges from 46.5% to 59.4%.

The family *Pyrinomonadaceae* (subdivision 4) is composed of the genera *Brevitalea*, *Arenimicrobium* and *Pyrinomonas*. Members of this family are gram-negative, non-spore-forming, non-capsule-forming aerobic chemoorganoheterotrophs that are unable to grow phototrophically, reduce nitrate or ferment glucose. They are mesophiles or thermophiles and tolerate a broad range of pH. Furthermore, they prefer complex proteinaceous growth substrates and have a variable capability to break down polymers. Their genomic G+C content varies from 54.7% to 66.9%.

The family *Acanthopleuribacteraceae* contains only the genus *Acanthopleuribacter*. Cells belonging to this genus are gram-negative, motile, strictly aerobic rods that are able to use α -D-glucose, L-alanine, hydroxy-L-proline, L-serine, L-threonine, inosine, uridine and thymidine for growth. The genomic G+C content of the type strain *Acanthopleuribacter pedis* is 56.7%.

The family *Holophagaceae* is formed by the genera *Holophaga* and *Geothrix*. Both are strictly anaerobic chemoorganotrophs that are non-spore-forming, gram-negative, mesophilic, neutrophilic, and non-motile. The genomic G+C content of the type genus *Holophaga* is 62.5%.

The family *Vicinamibacteraceae* contains the genera *Vicinamibacter* and *Luteitalea*. These bacteria are gram-negative, non-spore-forming, aerobic chemoorganoheterotrophs that are capable of growth on organic/nucleic acids and simple sugars but prefer complex proteinaceous compounds. They are neutrophiles that tolerate a wide range of pH and can be psychrotolerant or mesophiles. Their genomic G+C content varies from 64.7% to 65.9%.

A few genera are not associated with any of the described *Acidobacteria* families. The genus *Thermotomaculum* belongs to subdivision 10 and is an anaerobic heterotrophic thermophile that was isolated from a deep-sea hydrothermal vent. *Thermoanaerobaculum* is another strictly anaerobic, thermophilic and chemo-organotrophic genus belonging to subdivision 23 that was isolated from a freshwater hot spring. Finally, *Chloracidobacterium* is a thermophilic, anoxygenic, chlorophototrophic member of class *Blastocatellia* isolated from a hot spring.

The number of isolates and described genera of *Acidobacteria* has gradually increased due to insights into the metabolism of these bacteria provided by genomic and metagenomics studies, as well as improvements in cultivation methods. Currently, there are 43 complete genomes (29 *Acidobacteriia*, 3 *Blastocatellia*, 3 *Holophagae*, 6 *Solibacteres* and 2 unclassified *Acidobacteria*) in the NCBI database (NCBI Resource Coordinators, 2018) (Table 1). Further efforts to unravel the metabolism of uncultured microorganisms through modern technologies, such as high-throughput sequencing and nanoscale secondary ion mass spectrometry (NanoSIMS),

Table 1 *Acidobacteria* complete genomes listed in NCBI (<https://www.ncbi.nlm.nih.gov/genomes/GenomesGroup.cgi?taxid=57723>, December 2018)

may provide additional insights on how to cultivate novel genera, thereby increasing present knowledge on the characteristics and functions of members of the phylum *Acidobacteria*.

Isolation Methods

Culturing *Acidobacteria* from soils is not trivial and requires a combination of low nutrient concentrations and/or environmental extracts, complex polysaccharides (carboxymethylcellulose, microcrystalline cellulose, chitin, gellan gum, xylan and starch) as a carbon source, amendment of the growth medium with quorum-signalling molecules or catalase, and long incubation periods under non-standard CO₂ atmospheric conditions. The combination of those factors and conditions mimics the environmental conditions where *Acidobacteria* is found and thus will influence the recovery of acidobacterial isolates. Several low-nutrient or dilute culture media are used to isolate *Acidobacteria* strains, such as 1/10 diluted R2A, VL55, GYE, MM, PSYL 5 and SSE (soil solution equivalent). Frequently, the medium is composed of a mineral base, supplemented with yeast extract, trace elements, vitamin solutions and other growth factors, and solidified with either agar or gellan gum. For some strains of the genus *Granulicella*, the addition of SL-10 trace element solution can significantly enhance bacterial growth (Fig. 3). After isolation under low-nutrient conditions, *Acidobacteria* strains can often be transferred to richer media (e.g., TSA and R2A) for more convenient propagation.

Phages and Mobile Elements

Acidobacteria genomes vary greatly in size (Table 1). Many factors explain the variation of the size and plasticity of genomes, including gene duplication, rearrangement of genetic elements by phages, the presence of transposable and mobile elements and the presence of horizontally transferred genes. These factors are advantageous for the survival of *Acidobacteria* in different environments. The presence of prophages is common in acidobacterial genomes, including in *Acidobacteriaceae bacterium* KBS 146 and *A. ailaui* (subdivision 1), *Pyrinomonas methylaliphatogenes* K22 and *Chloracidobacterium thermophilum* B (subdivision 4), and *Thermoanaerobaculum aquaticum* (subdivision 23). However, these prophages differ from previously described microbial prophages. The prophage is typically located in the same region of the genome as mobile elements encoding transposases and integrases, suggesting that these genomic islands were acquired by horizontal transfer events. The presence of these extra genetic elements impacts the evolution and metabolic capabilities of *Acidobacteria* to cope with environmental conditions.

Carbohydrate Metabolism

Carbon usage is one of the physiological requirements for the description of new species in taxonomic studies, and therefore carbohydrate metabolism in *Acidobacteria* has been widely studied. Depending on the species and subdivision, *Acidobacteria* are able to use D-glucose, D-xylose, lactose, maltose, fucose, sorbose, cellobiose, glucose and xylose as carbon sources and can degrade simple and polymeric carbohydrates. The genomes of *Acidobacteria* include genes encoding pathways for the degradation of various polysaccharides (starch, cellulose, hemicellulose, laminarin, xylan, xyloglucan, and gellan gum), and physiological

Fig. 3 Growth curves of *Granulicella* (a) WH15 and (b) 5B5 strains on PSYL 5 liquid culture medium with different concentrations of SL-10 trace element solution: 1 ml/L (1X), 10 ml/L (10X) and 0 ml/L (0X). The error bar is the standard error of the mean and indicates differences in the response variable between different treatments.

studies have observed enzymatic activities such as β -D-glucosidases, endo- β -1,4-xylanase, gellan lyases, unsaturated glucuronyl hydrolases, and α -rhamnosidases. Metatranscriptome analyses have revealed the expression of functional acidobacterial glycosyl hydrolase (GH) families involved in the degradation of cellulose, hemicellulose and xylan, compounds that are rich in environments with high C:N ratios, such as tropical and temperate forests, tundra and peatland, where *Acidobacteria* are abundant and dominant.

Genes related to the biosynthesis, transfer, breakdown and/or modification of carbohydrates represent 5%–9% of acidobacterial genomes. The genomes of the non-soil isolates *G. fermentans*, *H. foetida* and *C. thermophilum* B have the lowest percentages of genes related to carbohydrate metabolism. The GH families related to polymeric carbohydrate degradation with the highest percentages across different acidobacterial genomes are GH109 and GH74. GH109 is an alpha-N-acetylgalactosaminidase (EC: 3.2.1.49) that acts on O-linked oligosaccharides, which are typically found in chitin, bacterial peptidoglycan and lipopolysaccharide, whereas GH74 is an enzyme family that targets the beta-1,4-linkages of glucans (polysaccharides of glucose). Various GH families involved in the degradation of beta-glycosidic bonds, typical cellulosic bonds, are also present in acidobacterial genomes. More specifically, GH5 is found across subdivisions 1, 3, 4 and 6, while GH8, GH9, GH44 and GH12 have only been detected in a few genomes of subdivision 1 (*T. sp.*, '*Ca. K. versatilis*', *T. gabretensis*, and *G. mallensis*) and subdivision 3 (GH9, '*Ca. S. usitatus*'). The GH3 family includes beta-glucosidase, an enzyme that hydrolyses glycosidic bonds in oligosaccharides to produce glucose, and is present in acidobacterial genomes, and the GH18 family includes putative chitinases that are present in all of *Acidobacteria* subdivision 1, two members of subdivision 3 ('*Ca. S. usitatus*' and *Acidobacteria bacterium* KBS 96), one member of subdivision 4 (*P. methylaliphatogenes* K22), one member of subdivision 6 (*L. pratensis*) and one member of subdivision 8 (*H. foetida*). The GH19 family of chitinases is found in *G. fermentans*, *P. methylaliphatogenes* K22, *L. pratensis*, *T. saanensis* and *E. aggregans*. The presence of chitinase genes indicates that chitin is used not only as a carbon source but also a nitrogen source.

Nitrogen Metabolism

All known acidobacterial genomes (Table 1) except *Thermoanaerobaculum aquaticum* have homologue genes for ammonia uptake, such as the ammonium channel transporter family (*amtB*), glutamate dehydrogenases (*gdhA* and *gdh2*), glutamine synthetase (*gltBD*) and glutamate synthase (*glnA*). Putative genes encoding assimilatory nitrate reductases (*NarR*), nitrite reductases (*NiR*) and nitrate/nitrite transporters are present in *T. roseus*, *Granulicella mallensis*, *Granulicella tundricola*, *Acidobacterium ailaui*, '*Ca. Solibacter usitatus*', *Pyrinomonas methylaliphatogenes*, *Luteitalea pratensis*, *Acidobacteria bacterium* KBS 96, *Acidobacteriaceae bacterium* KBS 146 and KBS 89 and *Terriglobus* sp. *NiR* genes have only been detected in *Acidobacteriaceae bacterium* KBS 83.

Among *Acidobacteria* subdivision 1, *G. mallensis* performs nitrate reduction, and *Acidipila rosea* and *Bryocella elongata* are also able to reduce nitrate to nitrite. Among other subdivisions, only *Geothrix fermentans* in subdivision 8 is able to reduce nitrate; this organism is an iron reducer that can use nitrate as an alternative electron acceptor. All of these *Acidobacteria* are able to use yeast extract and ammonium as preferred nitrogen sources. The genomes of subdivision 1 contain the *nirA* gene, which encodes nitrate reductase, suggesting that members of this subdivision may reduce nitrate to nitrite by the assimilatory pathway, followed by further reduction to ammonia and assimilation into glutamate. Nevertheless, direct uptake of ammonium seems likely as all genomes described to date (Table 1) appear to contain genes for the ammonia transporter channel (*Amt*) family (TC 1.A.11). Nitric oxide reductase genes (*norB* but not *norC*) have been identified in the *Koribacter versatilis*, *S. usitatus* and *G. fermentans* genomes. The *narG* operon encoding a membrane-bound respiratory nitrate reductase is present in the genome of *G. fermentans*. The genomes of *Luteitalea pratensis* (subdivision 6), *G. fermentans* (subdivision 8) and *Holophaga foetida* (subdivision 8) harbour genes encoding a dissimilatory nitrite reductase (*nrfHA*) that catalyses the reduction of nitrite to ammonia. Genes encoding dinitrogenase, a heterotetramer of the proteins NifD and NifK (genes *nifD* and *nifK*, respectively), and dinitrogenase reductase, a homodimer of the protein NifH (gene *nifH*), are only present in the genome of *H. foetida*. *Thermoanaerobaculum aquaticum* contains the *napA* operon, which is involved in dissimilatory nitrate reduction, and *G. mallensis* and *Acidobacteria bacterium* KBS 96 have similar assimilatory nitrate reductase genes (*nasA* genes) involved in dissimilatory nitrogen metabolism. The denitrification pathway cytochrome cd1-containing nitrite reductase gene (*nirS*) is absent in acidobacterial genomes, but the dissimilatory copper-containing nitrite reductase gene is present as a single copy, with the exception of two copies of *nirS* in the *Acidobacteria bacterium* KBS 96 genome. Although genes related to the nitrogen cycle are present in the genomes of *Acidobacteria*, there is no experimental evidence for a denitrification pathway in *Acidobacteria*. However, *Acidobacteria* can use both inorganic (ammonia and/or nitrate/nitrite) and organic (amino acids and other high-molecular-weight compounds) N sources. In addition, genes encoding specific transporters for amino acids, polyamines and organocations are overrepresented in genomes from terrestrial environments, in which bacteria use inorganic but also organic N sources via mineralization.

Sulphur Metabolism

Seven draft genomes recovered from metagenomic data from acid peatland suggest that *Acidobacteria* is involved in dissimilatory sulphur metabolism. Novel recovered *Acidobacteria* species show potential for dissimilatory sulphite (*dsrAB*, *dsrC*, *dsrD*, *dsrN*, *dsrT*, *dsrMKJOP*) or sulphate respiration (*sat*, *aprBA*, *qmoABC*, *dsr* genes) or encode *DsrL*, which is only found in sulphur-oxidizing microorganisms. The expression of acidobacterial *DsrAB* sulphur metabolism genes indicates new fundamental niches

for facultative anaerobic *Acidobacteria* in wetlands. In addition, *Acidobacteria* from wetlands encode enzymes that liberate sulphite from organosulphonates, suggesting that organic sulphur compounds can serve as complementary energy sources.

Exopolysaccharides

The *Acidobacteria* strains *Granulicella paludicola*, *G. pectinivorans*, *G. aggregans*, *G. rosea*, *Acidicapsa borealis*, *A. ligni* and *Terriglobus tenax* are capable of producing exopolysaccharide (EPS) in culture medium. In addition, acidobacterial genomes belonging to subdivision 1 (with the exception of *K. versatilis* strain Ellin345) contain genes involved in EPS biosynthesis, specifically those involved in cellulose synthesis. To date, acidobacterial EPSs have been isolated and chemically characterized only from two strains of *Acidobacteria* subdivision 1, *Granulicella* sp. strain WH15 and strain 5B5. These EPSs comprise heteropolysaccharides composed of 7 different monosaccharides. One of the functions of EPS is probably related to acidobacterial cell protection for long-term survival in soil. The production of large amounts of *Acidobacteria* EPS is related to abiotic stress, i.e., dominance of *Acidobacteria* in acidic environments and resistance to pollutants like uranium, petroleum compounds, linear alkylbenzene sulfonate and p-nitrophenol. In addition, acidobacterial EPS can emulsify different oils. *Granulicella* sp. WH15 and 5B5 strains, and the type strain of the genus *Acidicapsa*, *A. ligni* WH120T, produce EPS in the adhesion of bacteria to the plant root surface via biofilm formation and promote plant growth. The underlying mechanisms include acidobacterial production of the plant hormone-like auxin indole-3-acetic acid (IAA) and a siderophore that removes iron from the environment. Iron accumulation has been observed in *B. elongata* and was confirmed by the identification of genes encoding transport systems involved in translocation across the outer and cytoplasmic membranes, i.e., cobalamin/ Fe^{3+} -siderophore uptake transporters and Fe^{3+} hydroxamate transporters. Genomic analyses also suggest that *Acidobacteria* may release siderophores to scavenge iron from soil minerals by forming Fe^{3+} complexes that can be taken up by those transporters or use siderophores from other microorganisms.

Acidobacteria and Soil Ecosystems

Acidobacteria have the *qlcA* gene, which encodes a lactonase that degrades N-acylhomoserine lactones (NAHLs). Similarly, genes involved in polyketide synthesis (PKS) pathways were identified in *S. usitatus*. The identification of *mtaD* gene homologs encoding proteins involved in myxothiazol biosynthesis in isolates belonging to subdivisions 3, 4 and 6 suggests the widespread distribution of PKS pathways among *Acidobacteria*. Genes involved in PKS biosynthesis have also been identified in sequenced acidobacterial genomes, and the ubiquity of such pathways in this phylum suggests a role in the persistence, resistance and abundance of these bacteria in soil ecosystems.

Acidobacteria are predominant in low pH conditions, particularly members of subdivision 1. By contrast, some acidobacterial subdivisions have an aversion to low pH conditions in soil, whereas others, such as subdivision 6, can be either positively or negatively correlated with soil pH. The abundance of subdivisions 1, 2, 3, 12, 13, and 15 is negatively correlated with soil pH, whereas subdivisions 4, 6, 7, 10, 11, 16, 17, 18, 22, and 25 have positive correlations. A possible explanation may be increased cell specialization at more extreme pH, where closely related *Acidobacteria* may share similar cellular strategies to deal with discrepancies between intra- and extracellular pH.

Acidobacteria subdivisions 4 and 6 are abundant in soils with high Mg and Ni content, such as serpentine tropical savanna soils; subdivisions 4, 6, and 7 respond to decreases in soil aluminium in tropical soils; subdivisions 6 and 7 respond to high contents of soil Ca, Mg, Mn, and B; subdivision 10 correlates with soil factors linked to soil acidity such as pH, Al, and Al saturation; and subdivision 13 correlates with soil P, B, and Zn. Although subdivision 1 negatively correlates with P, C and N, members of subdivisions 5, 6 and 17 appeared to be highly abundant in more nutrient-rich soils.

The high number of ABC transport systems facilitates the high-affinity acquisition of a broad range of substrate categories, including not only sugars but also polyols, drugs, amino acids, peptides, siderophores and anions.

Conclusions

The high abundance and ubiquity of *Acidobacteria* in different environments, especially soils, raises questions about the physiological traits underlying this marked success. Genome sequences have provided important information, especially about *Acidobacteria* subdivision 1, the group for which the most pure cultures are available. However, for other subdivisions, information is scarce due to the difficulty of isolation and cultivation. The increased high throughput of shotgun metagenomic studies and associated postgenomic analyses have enabled the assembly of acidobacterial genomes from environmental datasets and yielded important genome trait information. However, cultivation efforts remain a top priority to provide the necessary material for physiological studies and confirmation of genomic predictions. The cultivation of *Acidobacteria* might be enhanced by the use of different techniques like micro-cultivation and single-cell sequencing as steps toward obtaining a more representative range of acidobacterial genomes. Despite their limitations, current genome sequences and the recovery of 16S rRNA genes from the environment provide important clues about the factors responsible for the successful adaptation of this phylum to harsh conditions, particularly in soils.

Increased knowledge of the genomic features of different *Acidobacteria* subdivisions is critical for understanding their survival, resistance, and persistence in soil as well as possible interactions of members of this phylum with other soil microorganisms. Therefore, additional experimental approaches combined with molecular studies, such as metatranscriptomic and stable isotope probing (SIP) analyses, are needed to obtain a fundamental understanding of the ability of *Acidobacteria* to utilize a wide variety of simple and complex carbohydrates as substrates, their roles in the C, N and S biogeochemical cycles, the production of EPS and secondary metabolites, their resistance to antibiotics, and the diversity of high-affinity transporters. In addition, further studies are needed to better understand the role of genetic mobile elements and prophages in shaping the genomes, metabolic versatility and evolution of *Acidobacteria* through the acquisition of novel metabolic genes.

Adaptations of Microorganisms to Low Nutrient Environments: Managing Life in the Oligotrophic Ocean

Sandra Martínez-García, University of Vigo, Vigo, Spain

Introduction

Inorganic and organic nutrients are essential for life as they are required for the biosynthesis of macromolecules and the construction of cellular structures. In nature, biological demand often exceeds nutrient supplies, resulting in the depletion of nutrients and a reduction of cellular processes. Already in 1905, Blackman defined nutrient limitation as the restriction of the growth rate of individual cells by low nutrient concentrations (Blackman, 1905), and much earlier Liebig's law of the minimum stated that it is the scarcest resource (limiting factor; Liebig, 1840), and not the total resources available, that defines the maximum amount of new biomass that can be formed (Cullen, 1991). As of today, it remains essential to distinguish between the influence nutrients have on defining growth rates as compared to determining standing stocks (defined by abundance or biomass) of organisms. Yet, it is important to consider not only the absolute concentrations but also the relative proportions of particular nutrients. In marine biology, the identification of elemental composition (stoichiometry) of phytoplankton cells as C/N/P = 106/16/1 (the Redfield ratio, Redfield, 1958) represented a breakthrough in understanding the nutritional demand of phytoplankton. Analyses of elemental composition of seawater and microorganisms remain essential for interpreting microbial growth and constraining fluxes in global biogeochemical cycles (Anderson and Sarmiento, 1994). If an element is present in substantially lower relative abundance than in the Redfield ratio it is highly likely to become a nutrient limiting microbial growth. Physical, chemical and biological factors collectively define the accessibility of nutrients to the living world.

A variety of habitats on Earth can be defined as low nutrient, or oligotrophic, environments, including lakes (Logue et al., 2012), soils (Hobbie and Hobbie, 2013), deep subsurface, groundwaters (Reed et al., 2010), deep oceanic waters (Arrieta et al., 2015) and most of the offshore surface ocean (Moore et al., 2013). Each of these systems merits a case study in itself. Throughout this article we will explain physiological and molecular adaptations that allow microbes to prosper in low nutrient environments. The article will focus on microbes in low-nutrient marine environments, particularly heterotrophic bacteria and photosynthetic cyanobacteria in the open ocean surface waters, but similar adaptations are widespread in microorganisms in other environments.

The Surface Ocean: The Coast-Open Ocean Continuum

The Physics Behind Nutrient Availability

The world ocean covers >70% of Earth's surface and with an average depth of ~3700 m the marine biome is the largest on our planet. In order to understand the biology of microorganisms inhabiting low nutrient (oligotrophic) open ocean regions, it is useful to consider that the open ocean represents one extreme on a continuum where the other extreme is the coastal nutrient rich waters (Fig. 1).

Physical forcing on the ocean sets the stage for ocean productivity, where land runoff, atmospheric deposition, ocean currents and wind driven water mixing determine the flux of inorganic nutrients. Particularly in the eastern boundary of oceanic gyres, winds displace surface water from the coast allowing dense, cold, nutrient-rich deep water to reach the surface. This process, called upwelling, "fertilizes" surface waters and promotes extraordinary biological productivity. Such productive regions include for example, the Peruvian coast and the coast off Northwest Africa. Coastal upwelling regions occupy only 1% of the ocean but account for an important fraction (up to 20%) of global fisheries (Kämpf and Chapman, 2016).

In comparison to coastal waters and upwelling zones, the subtropical gyres are stable environments located far from nutrient sources (continents). In the gyres temperature-driven stratification of the water column prevents nutrient-rich deep water to ascend, resulting in low nutrient concentrations in surface waters and therefore low biological production (Fig. 1). Nutrient inputs to these ecosystems do occur but are scarce and usually related to atmospheric deposition (Duce et al., 1991), mesoscale hydrographic structures like oceanic eddies (McGuillicuddy, 2016) and lateral advection processes (Letscher et al., 2016).

Nutrient Availability and Marine Microplankton

Nutrient availability determines the rate of solar energy-capture through photosynthesis, resulting in the organic matter production that fuels the marine ecosystem. In coastal surface waters, microbial biomass ranges from 30 to 100 mg C m⁻³, as compared to 6–20 mg C m⁻³ in open ocean waters (<0.02 mg C m⁻³ in the deep sea) (Karl and Letelier, 2009). As a consequence of the different levels of nutrient availability, the food webs in the open ocean and coastal environments are different (Legendre and Rassoulzadegan, 1995). Low-nutrient conditions in the open ocean select for very small phytoplankton primary producers and a dominance of microbial food webs in which the transfer of organic carbon to higher trophic levels is relatively inefficient. In such systems, most production is sustained by nutrients like ammonium (NH₄) from remineralization of autochthonous dissolved organic matter

Fig. 1 Global maps of (A) Surface chlorophyll *a* (Chl) concentrations (9 km MODISA OCI Chla mission composite) and; (B) Depth at which nitrate concentration equals 0.2 μM (ZNO_3). Chlorophyll variability in the oligotrophic gyres: mechanisms, seasonality and trends. *Frontiers in Marine Science* 2, 1; licensed under CC BY 4.0.

(DOM) (often referred to as “regenerated production”). An alternative source of reduced nitrogen (N) and carbon (C) in open ocean oligotrophic environments is atmospheric N_2 fixation by cyanobacteria (Karl and Letelier, 2008; Fig. 2).

High-nutrient conditions, in contrast, select for large phytoplankton cells and efficient herbivore food chains where phytoplankton are consumed by zooplankton which in turn are preyed upon by fish. These large phytoplankton, often heavily silicified diatoms, contribute importantly to the sinking of organic particles and thus to organic carbon export and burial at the bottom of the ocean – the so-called biological carbon pump – ultimately influencing climate through the sequestration of CO_2 from the atmosphere (Boyd and Newton, 1999). Photosynthetic production in coastal nutrient-rich systems is mainly supported by nitrogen in the form of nitrate (NO_3^-) (not immediately regenerated from DOM), driving so-called “new production”. It is in these rich coastal/upwelling areas where much of marine life as we often picture it thrives, with whales, sharks and dolphins and important fisheries (Fig. 2).

Thus, from coast to open ocean environments, a continuum of life spreads from areas dominated by large microalgae (e.g., diatoms and dinoflagellates) to open ocean environments dominated by small phytoplankton (e.g., *Prochlorococcus*) (Fig. 2). Similarly, heterotrophic bacteria inhabiting each of these environments can be expected to differ substantially with respect to physiological and ecological adaptations and evolutionary trajectories. In general, oligotrophic microorganisms, defined as those living in low nutrient environments and adapted to uninterrupted nutrient limitation, are able to maximize the import of inorganic and organic nutrients and utilize these resources conservatively (usually growing slowly). By contrast, copiotrophic microorganisms are those that are exposed to high nutrient concentrations and consume them rapidly, but are inefficient in the uptake of substrates at low concentration.

In the next section, we will focus on the description of bacterial adaptations to life in the oligotrophic surface ocean.

Fig. 2 Conceptual diagram displaying the coast-open ocean continuum. Alongshore, wind stress results in coastal upwelling, supporting production of large phytoplankton, zooplankton and fish. Abundance and size of microplankton decreases from coast to open ocean where intense stratification prevents mixing and nutrient input. Image courtesy of Carina Bunse.

Managing Life in the Oligotrophic Ocean

The Influence of Resource Limitation on Marine Bacteria

Microorganisms in the low-nutrient surface ocean are limited both in growth rates and in standing stocks of biomass by the supply of inorganic nutrients and organic carbon, often referred to as bottom-up control. Accordingly, microorganisms in these ecosystems devote major portions of their energy to the acquisition of nutrients (Lauro et al., 2009). Moreover, the low nutrient concentrations strongly influences the composition of the microbial community inhabiting these environments, with major portions of photosynthesis carried out by tiny cyanobacteria in the genus *Prochlorococcus* and strong dominance of SAR11 clade among the heterotrophic bacteria (Partensky et al., 1999; Morris et al., 2002).

Over the course of evolution, marine bacteria have developed a multitude of strategies to maintain viable populations and successfully compete for resources in low nutrient environments. The most obvious adaptation is the small cell sizes of microbes in the open ocean as compared to coastal representatives. This leads to higher surface to volume ratios that allow relatively more efficient nutrient uptake. Less obvious, but not less important, is that marine bacteria that are dominant in oligotrophic areas have greatly reduced genome sizes (down to below 2000 genes per genome), achieved through the loss of several metabolic pathways in order to increase metabolic efficiency. This process is known as genome streamlining (Lynch, 2006). In contrast, the larger genomes found among (larger-sized) bacteria in high nutrient environments encodes significantly more genes (reaching 3000 genes per genome and upwards). This provides a high metabolic flexibility, which is beneficial in environments with repeated blooms of phytoplankton and irregular but often repeated supply of resources (Luo and Morán, 2014).

The importance of light as an energy source in low-nutrient environments is evident, both for organic matter production through chlorophyll based photosynthesis – primarily by cyanobacteria but also by eukaryotic microalgae – and for light energy harvesting through rhodopsins and bacteriochlorophyll (i.e., photoheterotrophy; see Section “Light as an Energy Source to Photoheterotrophic Bacteria”). A tight coupling of light and bacterial metabolism (through primary production) was suggested early on as an adaptive advantage in the oligotrophic ocean (Gasol et al., 1998). Accordingly, the life of osmotrophic heterotrophs in the oligotrophic ocean (i.e., essentially bacteria and archaea) is tightly coupled with primary producers – Their main source of nutrition – much because of the extreme scarcity of bioavailable dissolved organic carbon (Morán et al., 2002; see Section “Dissolved organic carbon” on DOC). Indeed, recent high-resolution metatranscriptomics analyses in the Pacific show coordinated diel patterns in gene expression across multiple microbial species. Such diel periodicity appears more pronounced in oligotrophic than in nutrient-rich coastal environments (because of generally higher nutrient levels and/or allochthonous inputs of nutrients in the latter). Differences in diel dynamics in activity likely influence the timing and mode of energy and organic matter processing in the sea (Ottesen et al., 2014).

Different nutrients may restrict microbial growth in different regions of the surface ocean (Fig. 3). N and phosphorous (P) are often referred to as macronutrients to microorganisms, as they are the elements besides carbon that are required in highest amounts to build biomass. Macromolecules like proteins and DNA contain large portions of the cellular N and P, respectively. Heterotrophic bacteria also require a supply of organic carbon for growth (recall that photosynthetic microbes acquire C from fixation of CO₂). N availability limits primary production in major open ocean regions, for example the open Atlantic Ocean (Fig. 3). Still, in some areas of the ocean P is the primary limiting macronutrient, as in the Sargasso Sea and the Mediterranean Sea (Fig. 3). Although less is known about specific nutrient limitation of heterotrophic bacterial activity and growth throughout the world oceans, several studies have highlighted the importance not only of macronutrients but also of organic carbon limitation for marine bacterioplankton (Church et al., 2000; Pinhassi et al., 2006; Martínez-García et al., 2010). Also, co-limitation, the simultaneous limitation by two

Fig. 3 Global maps showing patterns of microbial nutrient limitation in the surface ocean. Backgrounds indicate annual average surface concentrations ($\mu\text{mol kg}^{-1}$) of (a) nitrate (divided by 16, the mean N:P ratio of organic matter) and; (b) phosphate. Symbols represent nutrient limitation (as inferred from chlorophyll and/or primary production increase after nutrient amendments): primary and secondary limiting nutrients are represented by the central and outer circles, respectively. Divided circles indicate potentially co-limiting nutrients. Distinct colours represent different nutrients: nitrogen (green), phosphorus (black), iron (red), silica (orange), cobalt (yellow), zinc (cyan) and vitamin B12 (purple). Figure from Moore, C.M., Mills, M.M., Arrigo, K.R., 2013. Processes and patterns of oceanic nutrient limitation. *Nature Geoscience* 6, 701–710; reprinted by permission from Springer Nature.

different elements, e.g., any pairwise combination of carbon, nitrogen or phosphorus, is widespread throughout tropical and subtropical environments (Saito et al., 2008). On the other hand, iron (Fe) limitation is crucial for phytoplankton growth in regions at higher latitudes like the Southern Ocean (Fig. 3; Moore et al., 2013). It should be kept in mind that the primary limiting nutrient can change across seasons as a function of hydrographic conditions – such changes impose a challenge on the microbial community that can contribute to structuring bacterioplankton succession patterns (Pinhassi et al., 2006).

In the following, we present the principal nutrients that often limit bacteria in low-nutrient marine environments. We will describe microbial adaptations to the acquisition of scarce nutrients retrieved from both laboratory experiments and field studies, and include studies that use gene expression profiling to interrogate bacterial strategies for growth and survival in low-nutrient environments.

Dissolved organic carbon

The main source of dissolved organic carbon (DOC) in the upper ocean is photosynthetic activity, released directly during photosynthesis or lost through food web interactions like viral lysis or zooplankton grazing and excretion. Through these processes around half (range between 30%–90%) of photosynthetically fixed organic C becomes DOC and is used by bacteria (Ducklow, 2000). In fact, the oxidation of DOC via respiration represents the main source of energy for heterotrophic bacteria in the ocean.

The highest DOC concentrations are found in the sun-lit surface waters (~ 60 – $90 \mu\text{mol/L}$ in the open ocean) and decrease with depth (to $\sim 40 \mu\text{mol/L}$ in the deep ocean) (Hansell, 2002). However, most DOC is resistant to microbial degradation on time scales of days to months/years, possibly due to its intractable chemical structure, and/or low energy and nutritional value (Hansell, 2013). The DOC pool can be tentatively separated into three fractions based on its spectrum of reactivity and bioavailability: labile (a few $\mu\text{mol/L}$), semilabile (20 – $30 \mu\text{mol/L}$), and refractory (ca. $40 \mu\text{mol/L}$) (Hansell, 2013). Note that, although the concentration of DOC in the labile fraction is very low, this fraction turns over very rapidly (i.e., high production and consumption rates), and thus accounts for an important fraction of bacterial carbon demand.

Recent data suggest that over the course of evolution, marine heterotrophic bacteria in the oligotrophic open ocean have developed a coordinated, cooperative activity for the utilization of marine DOC. This activity consists of a precise resource partitioning of DOC by different bacterial “specialists”, so that DOC turnover is mediated by a temporal succession of taxa, metabolic pathways, and chemical transformations (McCarren et al., 2010; Sosa et al., 2015; Teeling et al., 2012). For example, bacterial gene expression analysis in the North Sea showed pronounced dynamics in carbohydrate-active enzymes, especially TonB-dependent transporters, and in phosphate acquisition genes, “indicating that distinct populations of *Bacteroidetes*, *Gammaproteobacteria*, and *Alphaproteobacteria* are specialized for successive decomposition of algal-derived organic matter” (Teeling et al., 2012). Also in oligotrophic marine systems, polysaccharide utilization is important for nourishing marine bacteria (e.g., NOR5/OM60 clade *Gammaproteobacteria*) (Sharma et al., 2014). Experiments with water from the North Pacific Subtropical Gyre (NPSG) show that opportunistic *Idiomarina* and *Alteromonas* species initiate the processing of DOM by using TonB-associated transporters, nitrogen assimilation genes, and fatty acid catabolism genes. The resulting DOM is then attacked by *Methylophaga* using a suite of assimilatory and dissimilatory single-carbon metabolic pathways (McCarren et al., 2010). Single-carbon (C1) compounds may originate from polysaccharides containing a large fraction of methylated sugars (Quan and Repeta, 2007) and have gained increasing attention as being key for the turnover of DOC in marine environments.

Prochlorococcus can use the Pro1404 transporter to take up significant portions of glucose at nanomolar concentrations in the Atlantic Ocean (del Carmen Muñoz-Mar, 2012). Members of the SAR11 clade, being a cosmopolitan bacterial clade with some of the most abundant organisms on Earth (Morris et al., 2002), play a key role in the carbon cycle in low-nutrient seas. Their streamlined genomes encode membrane transporters (likely with high affinity) and metabolic pathways for a number of low molecular weight carbon compounds, including amino acids, sugars, carboxylic acids, and osmolytes (Giovannoni et al., 2005). SAR11 bacteria also utilize one-carbon compounds (e.g., methyl groups from methylated compounds) as a source of energy via the C1 tetrahydrofolate (THF) oxidation pathway (Sun et al., 2011). Experiments with the SAR11 clade model organism *Candidatus Pelagibacter ubique* show that the utilization of methylphosphonic acid (an organophosphorus compound shown to be produced by marine microbes (Metcalf et al., 2012)) results in the release of methane, providing an explanation for unexpected accumulations of methane in surface waters limited by phosphorus (Carini et al., 2014a). This indicates one of surely many dependencies of the carbon cycle on inorganic nutrients in the oceanic environment.

Nitrogen

N is available to marine microorganisms in several inorganic and organic forms. Nitrite and nitrate, the more oxidized forms of N, are usually found in very low concentrations in surface waters ($<0.1 \mu\text{mol kg}^{-1}$; Fig. 3 from Moore et al., 2013), although it is abundant in deep waters (below the photic zone). Ammonia is an important source of N in the surface oligotrophic ocean as it results from excretion processes and remineralization of DOM. Marine microbes in the oligotrophic ocean also acquire N directly from DOM (e.g., proteins dissolved in seawater), some of which is in highly labile forms such as urea, dissolved free amino acids (DAA), and nucleic acids (Sipler and Bronk, 2015). Urea, for example, is a potentially important nitrogen source in the ocean, and is used by marine cyanobacteria (Moore et al., 2002). Concentrations of dissolved organic nitrogen (DON) in open ocean surface waters are ca. $3\text{--}5 \mu\text{mol kg}^{-1}$ (Letscher et al., 2013) and rapidly decrease with depth below the photic zone.

Gene expression analyses show that a suite of N metabolism genes (ammonium transporter, *amt*; dissimilatory nitrite reductase, *nirK*; urea transporter, *urt*; ammonia monooxygenase subunits, *amoABC*) are among the most highly expressed genes in low-nutrient environments (Shi et al., 2011). The expression of these genes is usually related to N stress in the cell. Interestingly, successful dominant oligotrophic microbes like *Prochlorococcus* and SAR11 clade bacteria can alleviate N stress by utilizing a variety of available DON compounds (and consequently their expression of ammonium acquisition genes is strongly reduced) (Sharma et al., 2014). In fact, bacteria in the SAR11 clade show pronounced gene expression responses to N-limitation, with a redirection of metabolism to take up and utilize organic nitrogen compounds (Smith et al., 2013). N limitation can also be dealt with by modifying the elemental composition of cells. Thus, preferential use of certain amino acids for protein synthesis to reduce N content in proteins, is an adaptation to N limitation (Grzymalski and Dussaq, 2012). Reductions in the net metabolic N fluxes and the N content in cytoplasmic pools represent an adaptation of *Roseobacter* clade bacteria to N starvation (Chan et al., 2012). Moreover, these bacteria may utilize methylated amines (Chen, 2012), potentially contributing to their N budget.

DON can represent an important source of N also for picocyanobacteria, and it has been suggested that the ability to utilize amino acids could contribute to the success of *Prochlorococcus* in the oligotrophic ocean (Zubkov et al., 2004; Mary et al., 2008). Analysis of closely related strains of *Prochlorococcus* and *Synechococcus* ecotypes that differ in spatiotemporal patterns of appearance show that N sources may contribute to niche partitioning (Fig. 4; Moore et al., 2002). Similar to roseobacters and SAR11 clade bacteria *Prochlorococcus* ecotypes display distinct expression patterns for genes in N and C metabolism, depending on N availability (Tolonen et al., 2006). Genetic inventories show that urea and ammonium assimilation genes are widespread in naturally occurring *Prochlorococcus* populations. In fact, the *amt* gene (an ammonium transporter in bacteria) is the most highly transcribed N-related gene in *Prochlorococcus* populations in the open ocean, likely an adaptive mechanism to efficiently scavenge N (Shi et al., 2011). In addition, genes for growth on nitrate (e.g., *narB*) are present in some *Prochlorococcus* strains, indicating that nitrate at times could be important to these bacteria in the open ocean (Fig. 4) (Berube et al., 2015). Also *Synechococcus* strains, which form dominant

Fig. 4 Maximum specific growth rates (μ_{max}) of *Prochlorococcus* strains SB, MIT0604, MIT9301, MED4 and WH8102 when growing on ammonium (NH_4^+) or nitrate (NO_3^-). Error bars represent standard deviation; n.g., no growth. Growth rates were significantly different ($p < 0.05$) between different strains when growing on the same nitrogen source and also between biological replicates of the same strain growing in different nitrogen sources. Figure from Berube, P.M., Biller, S.J., Kent, A.G., 2015. Physiology and evolution of nitrate acquisition in *Prochlorococcus*. The ISME Journal 9 (5), 1195–1207; reprinted by permission from Springer Nature.

populations in coastal environments, utilize nitrate as N source. Thus, adaptations to different N-sources contribute to explaining differential spatiotemporal distributions of *Synechococcus* and *Prochlorococcus* populations in the sea (Moore et al., 2002).

Phosphorus

The main inorganic source of P in the ocean is the oxidized form: phosphate. As for nitrate, phosphate concentrations are low in surface waters ($<0.4 \mu\text{mol L}^{-1}$) (Fig. 3; Moore et al., 2013) and increase below the photic zone. A suite of uptake systems and metabolic pathways has evolved in marine bacteria to efficiently utilize different forms of phosphorus (both inorganic and organic), as seen from genome analyses and metatranscriptomics. Gene transcripts typically enriched in bacteria under P starvation include the phosphate-binding (*pstS*), permease (*pstC*), and ATP-binding (*pstB*) components of high affinity phosphate-specific ABC transporters (Martínez et al., 2013; Dyhrman et al., 2007). In addition, and as exemplified by *Prochlorococcus*, bacteria adjust their P uptake kinetics in response to P stress by increasing cell-specific affinity and maximum velocity of uptake for both inorganic and organic P (e.g., PO_4 and ATP) (Krumhardt et al., 2013). Interestingly, *Prochlorococcus* shows complicated acclimation and regulatory mechanisms to maximize growth and survival under P starvation and the expression of P stress related genes differs between ecotypes depending on the particular environment they thrive in (Martiny et al., 2006, 2009). Regarding utilization of more specific P-containing compounds, genes for utilization of phosphite (a reduced P compound) have been detected in *Prochlorococcus* and other marine bacteria (Martínez et al., 2012).

Besides inorganic P, P in organic compounds is also available to marine microorganisms (Karl and Björkman, 2015; Gómez-Pereira et al., 2013). A wide range of compounds is included in the dissolved organic phosphorus (DOP) pool: monomeric and polymeric esters, phosphonates and organic condensed phosphates (e.g., nucleic acids, phospholipids, phosphoproteins, sugar phosphates, and phosphoamides) (Karl and Björkman, 2015). DOP concentrations in surface oligotrophic oceans ranges from ca <0.1 to $0.3 \mu\text{mol L}^{-1}$, with extremely low values (50 nmol L^{-1}) in the eastern Mediterranean Sea, one of the most oligotrophic seas in the world (Karl and Björkman, 2015). Under P-limitation, marine bacteria frequently induce the transcription of genes encoding alkaline phosphatases (e.g., *phoA* and *phoX*; Martínez et al., 2013) which hydrolyze a broad spectrum of DOP compounds (Sebastián and Ammerman, 2009; Duhamel et al., 2010).

Recent research on P cycling by marine bacteria shows that phosphonates (Pn; reduced organic compounds containing P that represent one third of high molecular weight DOP) are an important source of P for marine microorganisms. Pn utilization genes are widespread and abundant among marine bacteria (including *Proteobacteria*, *Planctomycetes*, *Cyanobacteria*, and *Pelagibacter*) suggesting that Pn may be a key P source in P-limited surface oceans, as well as in the more P-rich deep-water column (Dyhrman et al., 2006; Sowell et al., 2009; Martínez et al., 2010). Different strategies have been suggested for the use of phosphonates including high-affinity transport and hydrolysis of phosphonate compounds by a C-P lyase pathway (Dyhrman et al., 2006; Martínez et al., 2013), a phosphonatase pathway (Martínez et al., 2010) and a periplasmic substrate-binding protein for Pn acquisition (Sowell et al., 2009).

To reduce their dependence on P, some bacteria have evolved the ability to adjust their elemental requirements through modification of macromolecular composition. One example is the synthesis of sulfolipids instead of phospholipids in *Prochlorococcus* in oligotrophic environments (Bertilsson et al., 2003; Van Mooy et al., 2006). Similarly, some marine bacteria can produce phosphorus-free membrane lipids as a strategy to cope with P starvation, as exemplified by SAR11 clade bacteria and several other marine bacterial groups (Fig. 5; Carini et al., 2015; Sebastián et al., 2016). Thus, the spatial and temporal variability in availability of distinct P sources, the different adaptations to utilize different forms of (in)organic P, and the ability to alter the cellular P content all contribute to regulate the cycling of P by microbes in the world ocean.

Micronutrients

The availability of trace metals (e.g., iron, manganese, cobalt, zinc, nickel and cadmium) and vitamins is crucial for determining the productivity in marine ecosystems (Falkowski et al., 1998; Morel and Price, 2003; Saito et al., 2002). Trace metals typically play a critical catalytic role in the reactive sites in enzymes, thus influencing redox reactions (Price and Morel, 1990; Morel et al., 1994). In the open ocean most of these vital metals are found embedded within organic compounds, which hinders the direct measurement of their concentrations and bioavailability (Wells, 2002). As compared to C, N and P, micronutrients have received fairly little attention regarding how their availability contributes to structuring microbial communities and their activity.

The importance of iron (Fe) as a nutrient is appreciated since long due to its critical role as a redox catalyst in photosynthetic and respiratory electron transport chains of phototrophic and heterotrophic prokaryotes, respectively (Tortell et al., 1999), as well as being required for enzymes in N_2 fixation (Falkowski, 1997). The main allochthonous input of Fe to the surface ocean is through atmospheric dust deposition, following long distance wind transport (primarily from continental deserts; Jickells et al., 2005). Fe concentrations in oceanic surface waters are extremely low, averaging $0.07 \pm 0.04 \text{ nmol L}^{-1}$, with ca. 99% of it found as organic complexes (Johnson et al., 1997; Turner and Hunter, 2001; Parekh et al., 2004). Fe limitation of marine productivity is extremely relevant in the so called High Nutrient Low Chlorophyll (HNLC) areas (e.g., the Southern Ocean), where macronutrients such as N and P are readily available for phytoplankton but growth is limited by the availability of Fe (Fung et al., 2000; Moore et al., 2013). In such areas also Fe limitation of marine bacteria has been observed (Church et al., 2000; Kirchman et al., 2000; Cochlan, 2001; Arrieta et al., 2004).

Interestingly, the Fe to C quota of bacterioplankton is about 1.5–2 times higher than that of phytoplankton (Maldonado and Price, 1999) and bacterioplankton may account for up to 70% of the biological Fe uptake in environments like the Subarctic Pacific (Tortell et al., 1996; Maldonado and Price, 1999). To cope with Fe limitation, marine bacteria synthesize siderophores - high-affinity

Fig. 5 Membrane lipid remodeling in heterotrophic bacterial communities from environmental samples in the Eastern Mediterranean in August (severe P-limitation) and September (alleviated P-limitation). (a) Contribution of intact polar diacylglycerol lipids (IP-DAGs) to the membrane composition in P-starved (black) and P-replete (white) *mesocosms*. Contribution of P-lipids was higher during September while contribution of non P-lipids (glycolipids and betaine lipids) was higher during August. (b) Contribution of non-P versus P-lipids during severe P-limitation (August) and alleviated P-limitation (September). (c) Bacterioplankton community structure at the time of sampling. Figure from Sebastián, M., Smith, A.F., Gonzalez, J.M., 2016. Lipid remodelling is a widespread strategy in marine heterotrophic bacteria upon phosphorus deficiency. The ISME Journal 10, 968–978; licensed under CC BY 4.0.

Fe-chelating compounds – that are released into the water (Granger and Price, 1999). The siderophores with bound Fe, in turn, are taken up by outer membrane proteins, the TonB-dependent outer membrane transporters (TBTs) (Moeck and Coulton, 1998). Both SAR11 clade bacteria and *Prochlorococcus* show significant changes in gene expression upon Fe deficiency, including genes for periplasmic iron binding proteins and iron transporters (SAR11) and ferredoxin and flavodoxin genes (involved in Fe-regulated responses in cyanobacteria) (Smith et al., 2010; Thompson et al., 2011).

The importance of vitamins and other organic molecules for the ecology of microbes in the ocean is being increasingly recognized. The availability of vitamins can be a limiting factor for growth of microorganisms in open ocean waters (Panzeca et al., 2006; Bertrand et al., 2007; Koch et al., 2011). Most of current knowledge on the role of vitamins in marine environments concerns B-vitamins (Sañudo-Wilhelmy et al., 2006; Panzeca et al., 2008, 2009; Bonnet et al., 2013), which generally speaking serve as cofactors for enzymes catalyzing biochemical reactions in central metabolism. Still, different vitamins play distinct roles in microbial physiology (e.g., B12 is required for methionine synthesis, whereas vitamins B1 and B7 are required for carbon fixation, fatty acid metabolism and amino acid metabolism) (Sañudo-Wilhelmy et al., 2014). Many microbes lack the ability to synthesize vitamins (as is the case for us humans) and need to obtain them from the environment – such organisms are referred to as vitamin auxotrophs. Recent evidence shows that only a fraction of marine bacteria counts with biosynthetic pathways for B1, B7 and B12 (76%, 78% and 37% of the more than 400 bacterial isolates studied, respectively) (Sañudo-Wilhelmy et al., 2014). It is likely that much smaller portions of natural bacterioplankton are vitamin synthesizers, given that for example SAR11 clade bacteria, one of the dominant bacterial groups in the open ocean, are B1 auxotrophs (Carini et al., 2014b). Yet, some heterotrophic bacteria crucially determine vitamin availability to the microbial food web by turning B1 precursors into B1 (Paerl et al., 2015). These findings suggest that an important portion of marine bacteria may eventually compete with phytoplankton for the uptake of these growth factors from the environment.

The number of recognized micronutrients that ultimately affect metabolism and growth of microorganisms in the open ocean is constantly increasing through new research on microbial interactions. In a recent ground breaking experiment, analysis of cocultures of the diatom *Pseudo-nitzschia multiseriis* with the *Roseobacter* clade bacterium *Sulfitobacter* sp. SA11 revealed that bacterial excretion of the hormone indole-3-acetic acid triggered diatom growth stimulation; and diatom release of tryptophan in turn signaled

improved growth conditions to the bacterium (Amin et al., 2015). New knowledge is much needed of the spatial distribution of different vitamins and growth factors, their concentrations, and their dynamics over different temporal scales (from days to months). Along with knowledge on which microbes are key producers of growth factors, this will bring a deeper understanding of how microbial interactions allow microorganisms to manage life in the low-nutrient open ocean.

Light as an Energy Source to Photoheterotrophic Bacteria

In addition to driving chlorophyll *a*-based photosynthesis (as found in most plants and phytoplankton), solar energy is a key energy source also to microorganisms with the light harvesting photosystems rhodopsin and bacteriochlorophyll (Fig. 6). The wide distribution and potential importance of bacteria with rhodopsin and bacteriochlorophyll in the marine environment was first highlighted in 2000 (Béjà et al., 2000; Kolber et al., 2000). Subsequent analysis of worldwide metagenomic datasets showed that on average 48% and 18% of bacteria contain rhodopsin and bacteriochlorophyll, respectively (Finkel et al., 2013). Obviously, photoheterotrophy - the ability of “heterotrophic” bacteria to complement their energy requirements with light - is a tremendous advantage in oligotrophic surface waters where growth and survival is often limited by availability of energy-rich DOC (Pinhassi et al., 2016; Koblizek, 2015). It should be noted that photoheterotrophs obtain energy from light but still rely on DOC for carbon (i.e., they cannot use carbon dioxide as their sole carbon source). Thus, light exposure allows ATP synthesis in these photoheterotrophs (i.e., photophosphorylation), which significantly reduces their dependence on respiration of DOC. Since a grand majority of DOC is typically respired to generate energy for metabolism rather than for building biomass, light harvesting can have a major impact on the fitness of bacteria.

Metatranscriptomics analyses confirm the ecological importance of rhodopsin- and bacteriochlorophyll containing bacteria (the latter carrying out aerobic anoxygenic phototrophy, AAP) (Frias-Lopez et al., 2008; Shi et al., 2011). In fact, rhodopsin genes – primarily proton pumping proteorhodopsins that ultimately generate ATP – are consistently among the most highly expressed genes in the surface ocean (Shi et al., 2011; Satinsky et al., 2014). Moreover, detailed analyses show pronounced variability in rhodopsin gene expression in many different bacterial groups over day-night cycles (Ottesen et al., 2013). A further indication of the importance of rhodopsins for obtaining energy is the high incidence of lateral gene transfer (LGT) of this photosystem: among Bacteria, between Bacteria and Archaea, and even between prokaryotes and eukaryotes. This is facilitated by the extraordinary genetic simplicity of the of rhodopsin photosystems (<10 genes). A major remaining challenge in understanding the life and success of microbes in low-nutrient environments is to obtain quantitative estimates of the energy harvested by photoheterotrophs (Pinhassi et al., 2016). Ultimately, such estimates could profoundly influence our understanding of how oceanic carbon cycling is regulated.

Deep Ocean Adaptations

Mesopelagic (200–1000 m) and bathypelagic (1000–4000 m) layers of the ocean are characterized by high pressure and relatively low temperatures, and whereas inorganic nutrient concentrations are high the availability of DOC is importantly limited. This DOC limitation arises due to strongly decreasing DOC concentrations with depth (i.e., with distance from the sun-lit surface ocean where DOC is freshly produced). Moreover, the DOC pool in deep waters is less bioavailable as it is composed of increasingly recalcitrant DOC after microbes have consumed the easily accessible and more highly energetic compounds (Jiao et al., 2010). There is ongoing discussion if this limited access to DOC is because it consists of recalcitrant materials or if it is due to the low concentration of the different DOC compounds (Arrieta et al., 2015). Similar to DOC concentrations, microbial abundance and production decline

Fig. 6 Growth of the *Bacteroidetes* isolate *Dokdonia* sp. MED134 in the light (yellow circles) and in the dark (blue circles). Also shown is relative expression of the proteorhodopsin gene in the light (yellow triangles) and in the dark (blue triangles). Error bars represent standard deviations. Figure slightly modified from Pinhassi, J., DeLong, E.F., Béjà, O., González, J.M. Pedrós-Alió, C., 2016. Marine bacterial and archaeal ion-pumping rhodopsins: genetic diversity, physiology and ecology. *Microbiology and Molecular Biology Reviews* 80 (4), 929–954, reproduced by permission from ASM Press and the author.

exponentially from surface to bathypelagic waters by ~ 2 – 3 orders of magnitude (Reinthal et al., 2006); yet, microbial diversity is surprisingly high in these environments (Sogin et al., 2006). The relative contribution of Bacteria to total prokaryotes decreases with depth as the proportion of Archaea, particularly chemoautotrophic Chrenarchaeota, increases (Teira et al., 2006). Important work on the genomics and ecology of natural communities and model deep-sea prokaryotes has contributed understanding of adaptations to the apparent lack of organic nutrients in these environments (Könneke et al., 2005; Vezzi et al., 2005; DeLong et al., 2006; Martín-Cuadrado et al., 2007; Konstantinidis et al., 2009; Walker et al., 2010).

In deep waters the absence of DOC production (ultimately from photosynthesis) is partly compensated for by chemolithoautotrophy. Chemoautotrophic metabolism (deriving energy from chemical reactions and synthesizing all necessary organic compounds from carbon dioxide) is suggested as a principal source of energy in deep waters. In fact, genes related to nitrate reduction and ammonium oxidation are commonly found in marine archaea (Könneke et al., 2005; Shi et al., 2011) and studies on the archaeon *Nitrosopumilus maritimus* have considerably broadened our knowledge on nitrification (i.e., ammonia oxidation) in these environments (Könneke et al., 2005; Martens-Habbena et al., 2009; Walker et al., 2010).

Recent studies have emphasized the importance to deep sea microbiota of sinking organic matter in the form of particles/aggregates produced in the euphotic zone (Baltar et al., 2009a; Shi et al., 2011; Swan et al., 2011). In general terms, genomes of several bacteria thriving in the deep-sea are larger and encode more rRNA gene copies, gene regulatory features, membrane transporters and a larger variety of metabolisms than the average surface ocean bacterium, features that are related to an opportunistic life style (Lauro et al., 2007; Lauro and Bartlett, 2008). Genetic analyses of deep-sea microorganisms further indicate the importance of a surface-attached life strategy, suggesting that deep-water prokaryotic activity to a large extent is associated with particles (López-López et al., 2005; DeLong et al., 2006; Lauro et al., 2007; Martín-Cuadrado et al., 2007).

Work with the deep-sea model bacterium *Photobacterium profundum* highlights the utilization of complex polymers for growth (e.g., chitin, pullulan, xenobiotics, and cellulose) and the presence of an amino acid fermentation pathway previously known only in anaerobes (Vezzi et al., 2005). Additionally, carbon monoxide oxidation has been suggested as an important additional energy source in the deep ocean (Martín-Cuadrado et al., 2007) and some deep-sea bacteria (the SAR324 clade) have the ability to utilize C1 compounds (Swan et al., 2011). In deep-sea bacteria, a number of membrane transporters are induced under high pressure, including ABC permeases related to nucleotide and inorganic ion transport and TonB type proton motive force-dependent transporters (Campanaro et al., 2005, 2008). Analyses of *Alteromonas macleodii* deep-sea ecotypes suggest they are adapted to rapidly exploit marine particles (García-Martínez et al., 2002; López-López et al., 2005; Ivars-Martínez et al., 2008; López-Pérez et al., 2013) and produce antibiotics-like metabolites to fight off competitors (Kimes et al., 2014; Mizuno et al., 2013). Interestingly, also free-living prokaryotes in the deep ocean have swimming abilities using flagella to approach particles or animals for subsequent attachment or colonization (Wang et al., 2008; Eloe et al., 2008). Furthermore, marine prokaryotes from deep waters are known to utilize extracellular enzymes that can be liberated as free dissolved enzymes and which are mainly utilized to access C in POM and DOM (Baltar et al., 2009b, 2010), possibly reflecting adaptations to rapidly respond to environmental change.

Conclusions

As shown in this article, there are plenty of distinct and complementary strategies that help microbes to survive in the low nutrient marine environment. Some microbes are clearly winners in this so-called hostile environment, like members of the SAR11 clade of *Alphaproteobacteria* and the cyanobacterial *Prochlorococcus* that are widespread dominants in the oligotrophic ocean. However, one may ask - is the oligotrophic environment really that “hostile” or “extreme” from these microbes’ perspective? In fact, a large majority of organism life - highly adapted to their environment - may see this as a perfectly “comfortable” environment. It appears like such “comfort” in oligotrophic waters is in part provided by a blurring of the classical distinction between hetero- and autotrophic life strategies, i.e., a wide spread of mixotrophy, where an important portion of heterotrophic bacteria are in fact photoheterotrophs relying on solar energy harvesting and photosynthetic cyanobacteria also utilize organic nutrients.

Undoubtedly, critical understanding of microbial oceanography and of microbial life in one of the largest low-nutrient biomes on Earth has been provided by international programs like the Joint Global Ocean Flux Study (JGOFS, see “Relevant Websites section”) and the establishment of regular long-term microbial observatories in open oceanic waters like the Hawaii Ocean Time Series (HOTS, see “Relevant Websites section”) and the Bermuda-Atlantic Time Series (BATS, see “Relevant Websites section”). Such time series are also necessary to provide knowledge on the effects of climate change on marine microbes, as climate change may affect nutrient cycling in the ocean by altering nutrient inputs (e.g., aeolian inputs, stratification, release from sediments) and metabolic processes key for the cycling of specific nutrients (e.g., denitrification, ammonia oxidation). The combination of field studies and experimental work with natural microbial assemblages and model marine bacteria, along with sequencing techniques like (meta)genomics and transcriptomics, constitutes a flexible platform to test hypotheses on microbial strategies for growth and survival in low nutrient ecosystems, casting light on microbial and biogeochemical process in the ocean.

Adaptive Radiation in Microbes

Felipe Dargent and Rees Kassen, University of Ottawa, Ottawa, ON, Canada

© 2019 Elsevier Inc. All rights reserved.

Glossary

Adaptive radiation The rapid diversification of a lineage into several distinct genotypes or species that use different ecological niches.

Character displacement More extreme phenotypic divergence in traits associated with resource acquisition when individuals of different genotypes or species occur in the same place than when they occur in separate places.

Disruptive selection Selection against types that have intermediate phenotypes. Individuals with extreme trait values have higher reproductive output than those with intermediate trait values. Also called diversifying selection.

Diversification The formation of two or more lineages from a single common ancestor.

Ecological opportunity The availability of previously inaccessible ecological niches or resources. Requires that an alternative abiotic or biotic resources exist, that the ancestral lineage is not excluded from the resource by its spatial or temporal distribution or by more efficient species, and that the ancestral lineage has or can evolve traits that permit use of the novel resource.

Niche A property of a genotype or species that describes the range of habitats or conditions that it can tolerate.

Defining Statement

This article provides an overview of adaptive radiation in microbes. We discuss the advantages of using microbial experimental evolution as a tool to explore adaptive radiation, present the main components of the theory used to explain this process, and evaluate the contributions of particular experiments to elucidate the ecological and genetic mechanisms that influence adaptive radiation in microbes.

Introduction

Adaptive radiation (AR) is the rapid diversification of a lineage into a range of phenotypically distinct genotypes or species that each occupy a different ecological niche. Evolutionary biologists have long been interested in AR because it is thought to be a major mode through which diversification happens. Iconic examples in multicellular organisms include sticklebacks in post-glacial lakes, the Hawaiian silversword alliance, Darwin's finches in the Galapagos islands, and cichlid fishes of the African Rift Valley lakes. The long generation times of these organisms preclude the direct study of evolutionary processes in real time, making it challenging to uncover the ecological and genetic mechanisms driving AR. A growing number of examples of AR in microbes are now available (discussed below) and these offer an outstanding opportunity to study the causes of AR because generation times are short enough, and population sizes large enough, to track evolutionary diversification directly in the laboratory. When coupled with whole genome sequencing to identify the genetic changes responsible for diversification, microbial systems provide an invaluable tool for gaining insight into the ecological processes and genetic mechanisms driving evolutionary diversification.

The Ecological Theory of Adaptive Radiation

The ecological theory of adaptive radiation, formalized by Schluter (2000), is the leading explanation for AR. Central to the theory is the concept of ecological opportunity, that is, the range of unused or underutilized niches or resources. Ecological opportunities become available when a lineage gains access to a novel environment where competitors are absent or when other species modify the environment to create new niches. When ecological opportunity is available, AR proceeds in three steps. First, differences in the conditions of growth across environments causes divergent natural selection leading to the evolution of locally-adapted specialist types (niche specialists), which by definition, trade-off fitness across alternative environments. Second, strong competition for resources generates disruptive selection against intermediate phenotypes that further exaggerates phenotypic and ecological divergence. The third step, unique to sexually reproducing organisms, is the creation of reproductive barriers as a consequence of ecological specialization that contributes to forming new species (speciation). In the predominantly asexual taxa used in microbial AR experiments, no such barriers exist and ecological divergence is directly linked to lineage diversification.

Advantages and Limitations of Using Microbial Systems to Test Adaptive Radiation

Advantages of microbial systems: The great advantage of microbial systems for studying evolutionary diversification is the ability to track the origins and fate of genetic variation associated with niche specialization directly through experiment. Measures of niche specialization come from estimating the fitness of an evolved strain against the ancestral strain from which it is derived through competition experiments, or pure culture measures of growth rate or yield across a range of environmental conditions. The large population sizes and rapid generation times of most microbes under laboratory conditions means that mutations are rarely in short supply and natural selection can be effective at generating adaptation. Niche specialization and ecological diversification can thus evolve very rapidly, within tens to hundreds of generations in some experiments. Identifying the genetic targets of adaptive diversification is now accessible to most labs through genome sequencing technologies, where the whole-genome DNA sequence of evolved populations or isolates is compared directly with that of the common ancestor. The repeated evolution of mutations at the same site in multiple independent replicates, or parallel evolution, is strong evidence that site is a target of selection.

Limitations of microbial systems: The study of AR in microbial systems suffers from an overrepresentation of particular species, especially *Pseudomonas fluorescens*, *Pseudomonas aeruginosa*, and *Escherichia coli*, that limits our ability to make strong, generalizable inferences. Others have criticized the use of microbial systems as models of AR in more complex organisms on two grounds. *First*, the majority of experiments are performed in lineages that reproduce asexually where mutation is the sole source of genetic variation, making it difficult to extrapolate results to sexual multicellular organisms where standing genetic variation is often more abundant, population sizes smaller and recombination is a key source of genetic variation. *Second*, and as we noted above, most studies of AR in microbes have not used sexually reproducing organisms, which means that the impact of ecological divergence on speciation in AR remains an open question. Some microbial systems capable of sexual reproduction, such as yeast, and species with moderate to high levels of horizontal gene transfer, such as *E. coli* Hfr strains, could be used to evaluate the role of recombination in ecological diversification.

Environmental Variation That Leads to Divergent Natural Selection

A necessary condition for ecological diversification is divergent natural selection generated by environmental variation, where different phenotypes are favored in different patches of the environment. Prolonged divergent selection leads to specialization, which means that the organism has high fitness in the patch it normally encounters but lower fitness in other patches. A typical experiment involves selecting an initially isogenic lineage in contrasting abiotic conditions of, for example, temperature, salinity, antimicrobial (antibiotic/antifungal) concentrations, or resource availability (differences in the amount or types of sugars) for hundreds or thousands of generations and then evaluating the degree of specialization in the evolved populations relative to each other and to the ancestor. Manipulations of the biotic environment, such as the presence vs. absence of predators and parasites, can also generate divergent selection.

Ecological Opportunity

Divergent selection can only be effective at driving diversification if ecological opportunity is available. This requires that alternative abiotic or biotic resources capable of generating divergent selection exist, the focal lineage has traits that allow the novel resource(s) to be used, and other species like competitors or predators that might prevent access to ecological opportunities are absent. In general, as the range of ecological opportunities increases, so too does the number of distinct types and the extent of phenotypic divergence among them in microbial AR.

Abiotic ecological opportunities can be present as a collection of distinct nutrients. For example, *P. fluorescens* and *E. coli* experiments show that increasing the number of distinct carbon resources in growth media leads to more genetic variation in resource use than evolution under a single carbon substrate. Spatial segregation of habitats can also play a role in AR, as Rainey and Travisano's (1998) seminal experiment illustrates. A single isolate of *Pseudomonas fluorescens* cultivated in a spatially homogeneous environment (created by agitating rich media on an orbital shaker) fails to diversify whereas the same genotype allowed to grow in the same medium without agitation, which affords spatial structure to the microcosm primarily through the formation of an oxygen concentration gradient, leads to the evolution of at least three ecologically and genetically distinct types over the course of ~1 week. These types are easily distinguished by their colony morphology (Fig. 1(A)): the ancestral broth-specialist 'smooth' (SM) morphotype, the 'wrinkly-spreaders' (WS) which produce high levels of a cellulose-like polymer and form a biofilm mat in the broth-air interface, and the 'fuzzy-spreaders' (FS) which are transient broth-air specialists that form loosely adhering rafts of cells that fall to the bottom after a WS biofilm collapses. Spatial structure is also necessary for the maintenance of diversity, as its removal (by shaking previously static cultures) leads to the loss of diversity within a few generations.

Some of the best examples of AR in the fossil record of multicellular species occur when ecological opportunities become available as a result of the absence of the usual suite of competitors faced by a lineage, as can occur following mass extinctions or colonization of species-poor islands. A similar process is seen in microbial ARs. When *P. fluorescens* diversifies in soil microcosms, which should more closely resemble their natural environment, they achieve a three-fold higher diversity in the absence of the resident soil-bacteria community. Despite the evolved diversity in soil being lower than in nutrient-rich broth, and mostly composed of the WS type and two SM types, the absence of interspecific competitors allows a more even distribution of distinct

Fig. 1 AR in the laboratory in two microbial model systems, as revealed by colony morphology on agar plates (top rows). (A) Morphotype diversity in *Pseudomonas fluorescens* evolved under static conditions in nutrient rich media; bottom row shows niche occupation by each morphotype grown on its own in static microcosms. (B) *Burkholderia cenocepacia* evolved on plastic beads in a flow-through system composed of nutrient rich media; bottom row shows each morphotype growing as a biofilm on test tube walls. In both systems spatial differences in distribution reflect difference in niche preferences. Figures from (A) Rainey, P.B., Travisano, M., 1998. Adaptive radiation in a heterogeneous environment. *Nature* 359, 69–72. and (B) Poltak, S.R., Cooper, V.S., 2011. Reprinted with permission of Springer Nature.

morphotypes than when the soil-bacterial community is present. Competitors can also prevent diversification by reducing ecological opportunity. SM morphotypes of *P. fluorescens* inoculated into static microcosms fail to diversify, for example, if WS morphotypes occupying the air-broth interface are already present.

Ecological Interactions That Promote Diversification

The striking phenotypic diversification associated with niche specialization in AR, and the unusually high rate at which diversification occurs, could be due to the combined action of divergent selection and disruptive selection (i.e., selection against intermediate forms) generated by ecological interactions. Competition is an ecological interaction that is the inevitable result of population growth on limited resources. Diversification results because lineages using a shared resource can reduce the antagonistic effects of competition for that resource by specializing on distinct resources. The tell-tale sign of diversification driven by resource competition is character displacement, where divergence in traits associated with resource acquisition is more pronounced in individuals that have evolved together compared to when they evolved separately. For example, Tyerman et al. (2008) selected *Escherichia coli* in minimal media supplemented with glucose and acetate. After 1000 generations genotypes that differ in the efficiency and dynamics with which they use the two carbon resources evolved. When these genotypes are further evolved separately for 200 generations their growth profiles become more convergent. When they are subsequently allowed to co-evolve together again for another 200 generations, the divergent phenotypes associated with resource use re-evolve. Similarly, *P. fluorescens* evolved in multi-carbon substrates show higher divergence in their metabolic phenotypes and fitness than among populations evolved in single-carbon substrates.

Enemies like predators and parasites can also generate disruptive selection leading to diversification in prey or hosts by generating selection for types that can avoid being eaten or parasitized. The predatory ciliate *Tetrahymena thermophila*, for example, can cause diversification of its *P. fluorescens* prey in minimal media by promoting the evolution of WS types that form a biofilm,

which provides a refugia against predation, at the air-broth interface. More commonly, however, predators and parasites tend to slow the rate of diversification by reducing victim density, and so weakening the strength of resource competition driving disruptive selection. In rich media, *T. thermophila* reduces *P. fluorescens* density by approximately an order of magnitude, slowing the rate of diversification.

Commensalistic or mutualistic ecological interactions can also create novel ecological opportunities and influence AR. One example is niche construction or facilitation, where the activities of organisms create novel niches and so generate the opportunity for divergent selection. Cross-feeding, where one type feeds on the metabolic by-products of another, is a well characterized form of niche construction in microbial systems. For example, in *E. coli* populations selected on minimal media with glucose as a sole carbon source a small 'S' morphotype sometimes evolves. The S morphotype feeds on acetate by-products of the ancestral large 'L' morphotype, and the two can stably co-exist. Niche construction is also seen during the formation of diverse biofilm communities in the opportunistic pathogen *Burkholderia cenocepacia*. Three distinct morphotypes (Fig. 1(B)) evolve following prolonged selection for cycles of colonization and growth on plastic beads in agitated nutrient media that show a regular colonization dynamic reminiscent of ecological succession. Following transfer to fresh media, 'wrinkly' morphotypes act as early surface colonizers, followed by the subsequent growth of 'ruffled' types, and then 'studded' morphotypes grow over-top the other two. Each type also distributes differently within the biofilm structure, 'ruffled' cells adhere well to the surface and spread sideways whereas 'wrinkly' cells adhere and grow mostly vertically. Interestingly, the total yield of diverse communities of all three types is higher than that expected from their combined yield when grown in pure culture, indicating that coevolved communities can be more productive.

The Genetics of Adaptive Radiation

Missing from the ecological theory is an explanation of how divergence in phenotype and ecology occurs at the genetic level and whether there are any general patterns and mechanisms that drive this process. Any genetic theory of AR must provide an explanation for how a lineage that gains access to novel ecological opportunities diversifies into ecologically distinct specialists from a founding lineage whose population size is likely to be small initially. The small size of the population is a consequence of it being mal-adapted to prevailing conditions, making it susceptible to extinction and limiting the amount of genetic variation accessible to selection. Models for the evolution of novel gene function, either through the modification of existing genetic material through mutation or the acquisition of novel (to the lineage) genes through horizontal gene transfer, provide a helpful starting place to explain how AR occurs at the genetic level.

Modification of Pre-Existing Genes

New genes and genetic functions are thought to evolve through a three-step process involving exaptation, amplification, and divergence (EAD). Most enzymes are exapted to some degree, meaning their native function also allows some fortuitous side-functions to be performed that allows a lineage to at least persist in a novel environment. Increases in fitness, and so population size, are caused by amplifying the production of limiting enzymes through either gene duplication or regulatory mutations that result in constitutive expression. The additional genetic material resulting from gene duplication and/or the expansion of the population allows functional divergence leading to niche specialization. A somewhat more complex version, the PEAD model, posits an additional step before exaptation called potentiation (the P in PEAD). Potentiation is the evolution of a genetic background that allows a lineage to access genetic variation relevant to the novel ecological conditions. Most lineages that undergo AR are likely to be 'pre-potentiated' in the sense that the genetic variation required for diversification is readily accessible when ecological opportunities become available. Key innovations, traits that contribute to diversification, may be the result of potentiation that occurs long before the ecological opportunities allowing diversification become available.

In the *P. fluorescens* AR, the transition from SM to WS involves often just a few nucleotide changes that cause loss-of-function mutations in one of several operons (*usp* 7 genes; *aus* 3 genes; or *mus* 1 gene) that comprise the first of a two-component signal transduction pathway allowing the cell to sense and respond to environmental signals. That these operons are present in the genome means they are, in effect, exaptations. Mutations in these operons, the most common being *usp*, cause amplification by constitutively expressing the signaling molecule c-di-GMP and causing a downstream operon, *wss*, to produce a cellulose-like polymer that is the key structural component of the WS biofilm. Functional divergence occurs because growth as a biofilm is traded-off against growth in the broth. The fact that several operons that influence the expression of c-di-GMP can be targeted helps explain the high repeatability of WS morphotype evolution in this system. Moreover, the fact that just one loss-of-function mutation is sufficient to cause the transition from SM to WS suggests the founding lineage is pre-potentiated and explains why this AR occurs so rapidly.

Horizontal Gene Transfer

The asexual nature of bacterial reproduction ensures that primary mode of inheritance is vertical, from parent to offspring. Nevertheless, novel genetic functions can be transferred 'horizontally' between lineages as well through conjugation (physical connections between bacterial cells), transduction (phage- or vesicle-mediated transfer), and transformation (uptake of extracellular DNA). Horizontal gene transfer (HGT) is known to be an important mode by which novel gene function can be acquired by a

lineage, as the spread of antimicrobial resistance on plasmids attests. However, the importance of HGT in generating ecological divergence associated with AR has been little studied in laboratory experiments, although, as we shall see in an upcoming section, it may be important in driving AR in nature.

Divergence via Niche Specialization

Fitness trade-offs across environments are the hallmark of niche specialization. Trade-offs evolve because selection is effectively 'blind' to the fitness effect of a mutation in any environment other than the one in which it is selected. Since many genes can have environment-specific effects, the increase in fitness in the environment of selection will usually exceed that in any other environment, resulting in specialization. Two genetic mechanisms can cause environment-specific effects: antagonistic pleiotropy resulting from functional interference, where a gene beneficial in one environment is deleterious in another, and mutation accumulation, where genes neutral in the environment of selection disrupt function in alternative environments. The rapidity of most ARs suggests that the niche specialization that evolves is most often underlain by antagonistic pleiotropy, as the WS example from the *P. fluorescens* radiation illustrates.

We can formalize the contribution of divergent selection to the evolution of niche specialization by extending Fisher's geometric model of adaptation, which sees adaptation as a series of mutation-driven steps in multidimensional trait space towards an optimal combination (the fitness optimum), to multiple optima (i.e., – environments; Fig. 2). In populations far from both optima, mutations that have beneficial effects in both environments are likely to be selected and fixed. As adaptation occurs to one environment, it will bring the lineage closer to its local optimum and farther from the alternate optimum, leading to specialization. Antagonistic pleiotropy leads to specialization when the lineage is located between two optima, since progress towards one optimum necessarily takes it further away from the other. Schick et al. (2015) tested this model by measuring the fitness effects of all mutations that arose in *P. fluorescens* during selection in three distinct carbon sources. Genome sequencing showed approximately three mutations per treatment for the end populations in each carbon source (xylose = 3.7 ± 0.2 , mannose = 2.7 ± 0.8 , glucose = 2.3 ± 0.8) after ~1000 generations. Consistent with the multi-optima version of Fisher's model, the pleiotropic effects of later stage mutations fixed in a focal environment were more often negative in the alternate environments than those of earlier stage mutations.

Do Laboratory Experiments Reflect Adaptive Radiation in Natural Microbial Systems?

While a growing number of examples of AR in microbes have been documented in various kinds of laboratory environments, the prevalence of AR in natural populations of microbes remains largely unknown. There is no reason why microbes would not frequently undergo AR outside the lab when ecological opportunities become available, as they might following, for example, a course of antibiotics that eliminates much of the competing microbiota alongside the targeted pathogen. However, comparative

Fig. 2 Mutational steps depicted by time sequences “t”. Degree of phenotypic change depicted by arrow length. Initial mutations might be more general adaptations to laboratory conditions (t_0 to t_1) and can lead to increased fitness in alternative environments (arrow moves closer to both Env. A and Env. B fitness optima “*”) although fitness increase is higher in the selection environment than the alternative environment (e.g. t_{1A} in Env. A); subsequent mutations that move the population closer to the optimum in the selective environment will decrease fitness in the alternative environment (e.g., t_{2B} moves further away from Env. A optimum as it approaches the Env. B optimum).

data supporting AR in wild microbial systems is rare, and the genomic tools to distinguish between lineages among recently diverged assemblages of co-occurring bacteria are still being developed. The most compelling example of a natural AR is the work of Hehemann et al. (2016) who documented genetic and ecological divergence of marine *Vibrionaceae* into at least three types that differ in their ability to degrade alginate, a glycan derived from algae. The 'pioneer' ecotype produces enzymes that diffuse into the alginate gel, breaking down polymers into more soluble forms and small oligomers. These by-product compounds constitute ecological opportunities that are exploited by two additional ecotypes, the 'scavengers' and 'harvesters'. 'Scavengers' are cheats that cannot degrade alginate directly and instead take up the small oligomers produced by pioneers. 'Harvesters' degrade larger alginate polymers, like pioneers, but their enzyme is attached to the cell rather than simply released into the surrounding media. Harvesters can also use small oligomers like scavengers. Interestingly, the lack of broadcast enzymes in harvesters means that they can capture more of the products of their enzymatic activity for themselves but at the cost of slower growth relative to pioneers, a trade-off that likely is important in supporting diversity in this system. Unusually, the genetic components allowing ecological differentiation seems to have evolved via extensive HGT rather than mutation-driven modification of pre-existing gene function. This observation suggests that we may need to refocus attention on the role of HGT in microbial ARs.

Another approach is to ask if laboratory AR experiments can recapitulate the spectrum of diversity observed in natural microbial populations. Schick and Kassen (2018) have demonstrated that, in one case at least, the answer is yes. The opportunistic pathogen *Pseudomonas aeruginosa* is known to diversify rapidly following colonization of the airways of cystic fibrosis (CF) patients into a range of phenotypic and genetically distinct lineages in a way that bears a striking resemblance to an AR. Schick and Kassen (2018) reasoned that the CF airway represents an ecological opportunity for a colonizing *P. aeruginosa* strain because of the spatial structure associated with different lung compartments, reduced dispersal due to the thick mucous layer in the lung lumen, and the rich spectrum of nutrients available. In an experimental test of this hypothesis, the authors showed that *P. aeruginosa* strain (Pa14) diversified rapidly (within ~220 generations) in environments that resembled the nutrient profile of the CF lung but not in simpler environments containing just a single carbon source. Importantly, diversification was accompanied by trait changes that recapitulate those often seen in isolates from CF patients, including increased biofilm formation, a loss of motility, and a reduction in some virulence factors. Given that these experiments were done in the absence of an active immune system and competing microflora that often characterize the CF lung, the results suggest that nutrient complexity is an ecological opportunity capable of driving *P. aeruginosa* diversification in the CF lung. Whether this diversity also contributes to the formation of chronic infections remains to be seen.

Adhesins During Infection

Anne-Marie Krachler, University of Texas McGovern Medical School at Houston, Houston, TX, United States

Introduction: The Function of Adhesion During Infection

Just as our macroscopic world is not static but in constant movement and flux, this is even more apparent at a microscopic level, where Brownian motion, the laws of mass action and forces such as shear and sedimentation guide the movement and fate of microbes.

In the context of the human host, bacteria can only succeed in colonizing and establishing an infection if they manage to overcome the body's attempt to remove them. In doing so, they have to resist mechanical forces associated with the body's physical clearance mechanisms in the form of fluid movement, including gastrointestinal movements, blood flow, or bladder filling and emptying, or air movement, including coughing and sneezing. While secretory shear stresses, such as in the intestine, are generally low ($0.5\text{--}5\text{ dynes cm}^{-2}$), and blood flow generates moderate shear stresses (between 15 and 60 dynes cm^{-2} in human arteries), some clearance mechanisms generate intense forces. The act of coughing, for example, can generate airflow rates of more than 500 L min^{-1} , producing shear forces of up to $1700\text{ dynes cm}^{-2}$. It is intuitive that, to withstand removal by these physiological processes, microbes have to adhere efficiently to host cell surfaces in order to colonize tissues. However, in addition to providing adhesive forces counteracting bacterial removal, the process of adhesion plays a number of roles during colonization and infection that are perhaps less intuitive: First, the sensing of physical forces and chemical features of adhesive surfaces deliver a unique set of environmental cues to the adherent microbe, allowing the organism to undergo an adaptive response, priming it for colonization and infection. Second, direct contact to host cell surfaces is often required to deploy secreted effectors and toxins that play important roles during pathogenesis. Third, adhesins can, in some cases, directly modulate host cell signaling in a way that facilitates bacteria-host interactions. We outline examples for each of these cases below, and refer readers to a recent, review for a more comprehensive discussion of these mechanisms.

Surface Sensing and Adhesion Lead to Bacterial Adaptations Facilitating Infection

Phenotypically, motile and sessile bacteria are distinct, and there are further adaptations that can be observed when comparing sessile bacteria on abiotic surfaces to those colonizing host tissues. So, how do bacteria distinguish between these environments to adapt their physiology? When a bacterium first encounters a surface, features of its cell wall, such as flagella, fimbriae and curli (Table 1 gives an overview of different pilus structures), act as probes that perceive both chemical and mechanical cues. Flagella have been implicated in initial surface sensing in a number of systems, although the sensory mechanisms involved are still not fully characterized and seem to differ between species. Type I and type IV pili also play a role in transitions to a sessile lifestyle upon initial attachment. Differences in pilus tension during retraction may transmit information about surface properties, resulting in changed levels of secondary messengers, such as cAMP and cyclic-di-GMP, and thus changes in transcriptional programs. The phenotypic features affected by surface sensing are specific to each microbe, but commonly include pathways involved in strengthening adhesion and optimizing nutrient salvaging within the host, or induction of secretion systems and toxins.

Contact-Dependent Secretion Systems Require Intimate Cell Contact

Many microbes use bacterial effectors to modulate host cell signaling in a way that promotes bacterial infection, for example by triggering or dampening inflammatory responses, manipulating intracellular trafficking pathways, or cytoskeletal dynamics. Most are deployed through specialized secretion systems which rely on direct host cell contact in order to function. Type three secretion systems (T3SS) for example, consist of a hollow channel and a tip, which forms a pore in the host cell membrane upon contact, allowing passage and direct transfer of effector proteins from the bacterial cytoplasm into the host cell. Although effector secretion can be artificially induced in some cases, effector translocation into host cells and full effector function are strictly contact-dependent. Due to requirements for high local concentrations to exert full activity, secreted toxins can show similar contact-dependence.

Adhesins as Modulators of Host Signaling During Infection

In addition to facilitating the translocation of bacterial effectors into host cells, adhesins themselves can act as "extracellular effectors" and can modulate host signaling processes to facilitate infection by binding to surface-exposed host receptors. Examples of this include integrins, which regulate diverse cellular functions, such as cell-substrate interactions and inflammatory responses, and are coopted by bacterial adhesins such as Yersinia invasin or FimH of uropathogenic *E. coli* (UPEC) to achieve bacterial invasion and spread. Another example is the *V. parahaemolyticus* adhesin MAM7, which modulates GTPase-driven host cytoskeletal remodeling and ultimately bacterial transmigration by engaging the host membrane.

Table 1 A brief overview of pilus structures, their assembly and function in Gram-negative and Gram-positive bacteria

	<i>Gram-negative chaperone-usher pili (fimbriae)</i>	<i>Gram-negative type IV pili</i>	<i>Gram-negative curli</i>	<i>Gram-positive pili</i>
Prominent examples	Type 1 pili in UPEC, P pili in <i>Pseudomonas</i>	<i>Pseudomonas</i> PAK pilus; <i>V. cholerae</i> TCP	<i>E. coli</i> and <i>Salmonella</i> curli	<i>C. diphtheriae</i> and <i>Lactobacillus</i> Spa pili
Morphology	Rigid helical OM anchored structure, 1–2 μm in length	Flexible, sometimes retractable structure, both IM and OM anchored, 1–several μm in length	Coiled, amyloid structure; 1–2 μm in length	Flexible rod, 0.3–3 μm in length
Subunits	1 major pilin forming the helical body; 3–4 different minor pilin subunits	>10 and up to 30 different subunits	2 curlins: major (amyloid forming) CsgA, minor (nucleator) CsgB, 4 assembly factors (CsgCEGF)	2–3 pilins, 1–4 assembly factors
Biogenesis	Through the chaperone-usher pathway (Sec- dependent type V secretion); noncovalent assembly through polymerization of >1000 pilin subunits into a helical body; capping by minor pilins and an adhesive tip protein	Type II secretion system	Extracellular nucleation-precipitation (type VIII secretion) of the major pilin, CsgA, into a cross- β -structure	Sec-dependent secretion, folding and membrane insertion of pilins by the thiol-disulfide oxidoreductase MdbA, sortase-dependent polymerization (covalent cross-linking) and anchoring of the pilus to the peptidoglycan layer
Adhesin	Lectins: e.g., FimH (type 1 pili), PapG (P pilus)	Both major and minor pilins are adhesive, but only distal subunits are functional adhesins	CsgA	Lectin-like tip adhesin (e.g., SpaC)
Host receptors	Mannosylated glycolipids and glycoproteins	Asialo-GM1, asialo-GM2 glycolipids	Extracellular matrix proteins (e.g., fibronectin, laminin, plasminogen)	Glycoproteins (e.g., mucin)

Throughout this chapter, we will discuss a variety of examples for specific adhesion/receptor pairs, highlighting mechanisms of adhesion from a biochemical perspective as well as downstream consequences of adhesion on regulation of host and bacteria cellular function and how these phenotypic changes facilitate colonization and infection. We will herein focus on bacterial adhesion to the human host and refer the reader to other sources for adhesion to abiotic surfaces or viral and protozoan adhesion mechanisms.

We attempted to organize the chapter by cell types, rather than bacteria, to highlight preferred targets for bacterial adhesion within a tissue. We think this will highlight how microbes have at times evolved common strategies to target a certain tissue, while at other times they purposefully target distinct receptors within a tissue to achieve different outcomes (invasion versus evasion, attack versus subversion, etc.). At the same time, we will try to point out that, while some host receptors are distinct, there is some overlap in receptors, or more generally, functional groups recognized by specific adhesins, in different cell types. Our understanding of these shared and distinct features and mechanisms of adhesion-receptor interactions helps to make sense of key characteristics of infectious agents, such as mode of infection, host and tissue tropism, mechanisms of spread and disease symptoms, and ultimately, ways to prevent and treat infections.

Epithelial Cells

Epithelial cells, such as keratinocytes, barrier epithelial cells, or brush border cells, form a protective lining on many body sites, including the skin, respiratory tract, urogenital tract and gastrointestinal tract. Beyond their role as a physical barrier, they fulfill important roles in relaying information derived from environmental cues that result in physiological responses, such as assimilation, secretion and immune regulation. Glycoproteins are abundant on epithelial surfaces, and the O-linked glycans within them exhibit a tremendous variety both in terms of their chemical identity and their sequence and structure. As such, they are frequently coopted as adhesion receptors by both fimbrial and nonfimbrial lectin-like bacterial adhesins. Below we will discuss the spectrum of their binding modalities and the role this plays in determining tissue and host tropism.

Bladder Epithelium

The bladder epithelium lines the urinary bladder, a hollow muscular organ that collects urine from the kidneys and regularly purges it. This creates a dynamic force environment, with regular changes between quasi-static and high-shear stress conditions and pH

ranging from 4.8–8.0. One of the best characterized bacterial adhesins, the adhesive tip protein FimH located at the tip of type I pili, is a key determinant of bacterial adhesion to the urothelium. Type I pili are wide-spread across Gram-negative bacteria. These pili are assembled via a dedicated chaperone-usher pathway consisting of a periplasmic chaperone that delivers pilin subunits to the outer membrane usher protein, which assembles them into a filamentous structure protruding from the bacterial cell surface. FimH consists of a C-terminal pilin domain required for polymerization and assembly, and an N-terminal jelly-roll domain with lectin function. FimH specifically recognizes D-mannosylated receptors, which allows binding of uropathogenic *E. coli* (UPEC) to uroplakin 1a, a glycoprotein expressed on the urothelium displaying high levels of terminally exposed mannose residues (located on Man(6)GlcNAc(2) to Man(9)GlcNAc(2)). FimH forms a unique catch-bond with mannose and undergoes conformational changes under high shear stresses, increasing the affinity for its receptor and allowing bacteria to withstand physical clearance upon urine purging. Uroplakin 1a is a tetraspanin (TSPAN21) associated with membrane lipid rafts, and UPEC have been shown to invade bladder epithelial cells in a caveolin and raft-dependent manner. FimH also cooperates with pathovar-specific pili, such as CF (colonization factor) pili of enterotoxigenic *E. coli* (ETEC), to facilitate colonization of the intestinal tract, and the fim operon encoding for type I pili is upregulated during GI tract infection.

Kidney Epithelium

UPEC encode for a second type of fimbrial adhesin, PapG on the tip of P pili. P pili are largely analogous to type I pili and are also assembled by the chaperone-usher pathway (Table 1). They are encoded by the pap locus. In contrast to FimH, PapG specifically recognizes galabiose containing glycosphingolipids, primarily found on the kidney epithelium, and has a shear-sensitive slip-bond, adapted to the low-shear environment in the kidneys and allowing for better bacterial dissemination.

Intestinal Epithelium

The intestinal epithelium is made up of enterocytes, which are the most prominent cell type and function mainly in nutrient absorption, as well as different types of secretory cells, including goblet cells (mucus secreting), enteroendocrine cells (hormone secretion), paneth cells (antimicrobial peptide secretion) and cells with immunomodulatory functions (e.g., M cells, Tuft cells). Below, we describe only adhesive mechanisms ascribed to cell-associated receptors, while a whole subsequent section is dedicated to adhesion to secreted mucins. Although most intestinal bacteria are restricted to the intestinal lumen and loose mucus layer covering the intestinal tract, some bacteria are capable of migrating through or degrading the mucus layer and adhering to the underlying intestinal epithelium. As is the case with other epithelial cells, this adherence is largely mediated by interactions between bacterial lectins and glycosylated host receptors. Enteroaggregative *E. coli* (EAEC) produce aggregative adherence fimbriae (AAF), which assemble via the chaperone-usher pathway and belong to the Afa/Dr. family of adhesins. Their host receptor is the epithelial transmembrane mucin Muc1, and sialoglycosylation of Muc1 is important for AAF adherence. Adherence of EAEC to Muc1 induces host cellular signaling which increases Muc1 expression, leading to positive feedback for bacterial adherence. On the other hand, the AAF-Muc1 interaction also increases pro-inflammatory signaling and enhances neutrophil recruitment and migration across the epithelium. Salmonella express a nonfimbrial lectin-like adhesin, SiiE, which recognizes *N*-acetyl-glucosamine and α 2,3-linked sialic acid on intestinal epithelial cells. SiiE is secreted in a type I secretion system-dependent manner, contains 53 repetitive bacterial immunoglobulin (BIg) domains, and with 595 kDa represents the largest protein expressed by Salmonella. Recent studies by Kohler and colleagues have demonstrated the receptor for cholera toxin B subunit adhesion involves binding to glycoproteins, not proteins, and that fucosylated structures promote entry of cholera toxin into colonic epithelial cells.

Gastric Epithelium

The gastric epithelium is composed of columnar and a variety of secretory epithelial cells, overlaid by a mucus layer. Together, the secretions of the gastric epithelium create a pH gradient, ranging from extremely acidic conditions (pH $\sim$ 1.5) in the gastric lumen, to a neutral pH at the epithelial surface. *Helicobacter pylori*, which infects half the world's population and is a leading cause of gastric ulcers and gastric cancers, adheres to the gastric epithelium via the mucin Muc5AC. Approximately 20% of *H. pylori* adhere directly to the gastric epithelium, while the residual population colonizes the mucus layer. They do so via a range of adhesins, including the autotransporters LabA, which recognizes a GalNAc β 1–4GlcNAc motif in Muc5AC, and BabA, which recognizes terminal Fuc, GlcNAc and Gal residues of Lewis(b) antigens on Muc5AC. In contrast to other lectins, such as FimH or PapG, no structural changes are induced upon carbohydrate binding. Instead, binding of BabA is pH sensitive; binding is strong at neutral pH conditions close to the epithelium but is of low affinity under acidic pH conditions, meaning *H. pylori* can escape upon shedding of mucus or cells into the gastric lumen. Interestingly, *babA* expression can be transiently lost, either by phase variation or by gene conversion, in which the paralog *babB* recombines into the *babA* locus. It is not known what selective pressures drive these expression changes, since it is independent of binding to Lewis(b) antigens, but they are recognized as a mechanism to adapt to host-specific variations in the intensity of pro-inflammatory responses to gastric infection. Not all adhesins mediating attachment to epithelial cells rely on lectin-carbohydrate interactions. *H. pylori* HopQ, for example, uses host receptors of the carcinoembryonic antigen-related cell adhesion molecule family (CEACAMs). HopQ specifically binds to the N-terminal IgV-like domain of CEACAM1, CEACAM3, CEACAM5 or CEACAM6 proteins, thereby enabling translocation of the major *H. pylori* virulence factor CagA into gastric epithelial cells. The HopQ-CEACAM interaction is characterized by a remarkably high affinity (K_D from 23 to

268 nM), which is independent of CEACAM glycosylation. HopQ deletion reduces CagA translocation, and inflammation and colonization in vivo.

Keratinocytes

Keratinocytes are epidermal-derived epithelial cells, which permanently exit the cell cycle and migrate to the epidermal surface, where they fulfill their function as the body's outermost barrier against environmental insults. They distinguish themselves from other cell types by the expression of keratins, which are often used as receptors by bacterial adhesins. The *S. epidermidis* serine-aspartate repeat (Sdr) family adhesin SdrF is a multi-ligand MSCRAMM (microbial surface components recognizing adhesive matrix molecules) and binds both keratin 1 and 10 (via its A and B domains), and $\alpha 1$ and $\alpha 2$ chains of type I collagen (via its B domains). Group A Strep, such as *S. pyogenes*, produce sortase-dependent cell wall-anchored pili displaying a minor adhesive pilin, Spy0125, that binds keratinocytes in a very distinctive, covalent manner. Spy0125 is a four-domain protein, comprised of two Ig-type CnaB domains and two thioester domains (TEDs). The folded adhesin forms an intramolecular thioester bond, which enables the protein to distinguish between binding of soluble and surface-immobilized ligands: Binding to soluble amine containing ligands, such as histamine, leads to attachment of the thioester via the ligand's amine and formation of an intermolecular isopeptide bond. This bond, however, is extremely transient, since solute binding does not exert force on the adhesin and the Spy0125's cysteine, which remains in close proximity, rapidly reforms the thioester bond and rejects the ligand. In contrast, binding of a surface-attached amine containing ligand, such as a host surface protein, distorts the adhesin upon covalent binding, leaving the cysteine unable to re-establish the original thioester and making the interaction extremely stable.

Mucus and Mucin-Producing Cells

Mucins are high molecular weight glycoproteins produced by certain subtypes of epithelial cells that are specialized in exocrine secretion and produce the mucus layer. To date, 21 different mucins have been identified—seven of them (including the adhesin target Muc1 mentioned above) are integral transmembrane proteins, while the rest are excreted. Excreted mucins are the main structural components of mucus, a highly hydrated gel consisting of structural proteins (mainly mucins), salts, and antimicrobial enzymes and peptides. Mucus is a continuously turned-over layer covering the gastrointestinal, respiratory, and urogenital epithelium, and serves both as a protective barrier keeping microbes at a distance from the epithelial surface, as well as a diverse niche supporting microbial growth. The entire gastrointestinal tract is covered by a protective mucus layer, but its composition and thickness vary dramatically. While the stomach mucus layer is approximately 1 mm thick in humans, the mucus layer is thinner in the intestinal tract, with an average thickness of 100–150 μm in the colon and rectal region.

Muc5, Muc7, and Muc19 are the predominant structural salivary mucins, and play an integral role in protection of the oral cavity against colonization by cariogenic bacteria. *Streptococcus mutans*, the main agent of tooth decay, produces several surface glycoproteins (e.g., the serine-rich repeat (SRR) proteins GspB and human salivary antigen, Hsa) which in the absence of a capsule can mediate adhesion to salivary mucins and mucin-mediated bacterial aggregation, keeping the bacteria from adhering to the enamel. The interactions are mediated by sialoglycan modifications on the mucins: While GspB selectively binds sialyl-T antigen, Hsa displays broader specificity, including to sulfated glycans. Sialoglycan binding is mediated by a conserved domain that is structurally similar to the glycan-binding module of mammalian Siglecs (sialic acid-binding immunoglobulin-like lectins), including an arginine essential for sialic acid recognition.

The mucus layer of the stomach consists mainly of Muc5 and Muc6. BabA mediates binding to Muc5 both on epithelium associated mucin and shed mucus and has low affinity at low pH conditions (as discussed above). *H. pylori* also expresses a sialic acid binding adhesin (SabA), and the contribution of SabA to *H. pylori* adhesion increases in gastritis. While intimate association of *H. pylori* with the gut epithelium is necessary for translocation of type IV secreted effectors, such as CagA, into host cells, sensing of mucins by *H. pylori* creates positive feedback by upregulating expression of BabA and CagA. There is also evidence that *H. pylori* infection changes the glycosylation pattern of infected individuals displaying intestinal metaplasia while asymptotically infected individuals had glycosylation patterns similar to uninfected controls, suggesting that *H. pylori* and the human host are engaged in a tug-of-war resulting either in alteration or adaptation of gastric mucus upon infection.

Intestinal mucus consists of two structurally distinct layers, an inner, epithelium associated layer and an outer luminal layer that is looser, more hydrated and subject to rapid turnover (in the order of 4–6 h). The structural mucin Muc2 forms the basis of the mucus layer covering the small and large intestine and is produced by goblet cells; goblet-, mucosal and absorptive epithelial cells synthesize the apical membrane-bound mucins Muc1, Muc3, Muc4, Muc12, Muc13, and Muc17. While the inner layer is devoid of microbes in healthy individuals, the outer mucus layer provides the main adhesive substrate and a growth niche for the intestinal microbiota. As such, most intestinal commensals express adhesins that recognize mucins.

One of the best characterized mucus adhesins in commensal bacteria is the canonical mucus binding protein MUB expressed by Lactobacilli, such as *L. reuteri*. MUB is a ~350 kDa modular protein forming extended fibrils and consists of an N-terminal domain of unknown function and 14 Mub1 and Mub2 type repeats at the C-terminus involved in mucin binding. Although both types have divergent sequences, their overall structures are well conserved. Binding of Mub domains to mucin is mediated by individual interactions by multiple Muc repeats and terminal sialoglycan modifications on mucin. Gram-positive pili (Table 1) also adhere to mucins via the adhesive pilus protein, SpaC. *Lactobacillus rhamnosus* express 10–50 pili per cell, with lengths up to 1 μm . Their major

structural component is SpaA, while SpaB and SpaC are minor pilus components integrated into the pilus at a ratio of 5:1:2 for SpaA:B:C. Unlike in Gram-negative pili, SpaA, B, and C are covalently cross-linked via isopeptide bonds giving them exceptional mechanical strength, while the Ig-type CnaA domains within individual pilins allow the pili to dissipate mechanical shocks without breaking. SpaC contains additional adhesive domains, including a von Willebrand factor A (vWFA) domain, and SpaC is found over the entire pilus length as well as a tip protein. Interactions between SpaC and mucin are likely mediated by lectin-glycan interactions; this is supported by the fact that SpaC itself is glycosylated and also mediates cell aggregation through homophilic recognition. While individual SpaC molecules display fast dissociation from mucin, multiple SpaC molecules along the pilus engage mucin in a zipper-like fashion, allowing bacteria to dynamically explore their niche but also to persist in the mucus layer. Enterohemorrhagic *E. coli* (EHEC) and enteropathogenic *E. coli* (EPEC) are a main cause of diarrheal disease as a result of food-borne infection in the Western world or in children without access to sanitized water, respectively. Both EHEC and EPEC adhere to Muc2 and adhesion depends on the presence of mucin-type core 2 O-glycan. Muc2 secretion is a double-edged sword for the host: On the one hand, Muc2 is a receptor that enables EHEC and EPEC attachment. On the other hand, bacterial adhesion to Muc2 also acts as a decoy keeping epithelial surface colonization at bay, and in the absence of Muc2, EHEC or EPEC exposure leads to high host morbidity and mortality. Both types of infection have the potential to stimulate mucin overproduction. EHEC adherence to intestinal epithelial cells stimulates the production of pro-inflammatory cytokines (e.g., TNF- α , IL-1 β , IL-8), which stimulates Muc2 expression and enhances EHEC clearance. However, the translocation of EHEC T3SS effectors into epithelial cells attenuates inflammatory signaling through ERK1/2 and PI3K/Akt, which partially counteracts Muc2-mediated clearance. Some atypical EPEC strains also induce hyperexpression of mucins, particularly the secreted Muc2 and Muc5 as well as the membrane associated Muc3 and Muc4, which act as receptors as well as growth substrate for those strains.

Several adhesins have been described in EHEC and EPEC but recently, the multivalent adhesion molecule (MAM) YebT expressed by commensal as well as pathogenic *E. coli* was shown to recognize 3-O-sulfogalactosyl moieties on host receptors, including Muc2. Interestingly, sulfatase production by some commensals such as *Bacteroides thetaiotaomicron*, depletes sulfoglycan modifications on mucin, thus making the mucus layer more permeable to *E. coli*. Enterotoxigenic *E. coli* (ETEC) express several adhesins that enable them to bind mucins, including the conserved two-partner secreted adhesin EtpA that localizes to the tip of ETEC flagella, creating a bridge between the bacterial surface and its host receptors, Muc2 and Muc3. EtpA recognizes a conserved, GalNAc containing glycosylation pattern on Muc2 and Muc3. Hypoglycosylation in a glycosyltransferase deficient host background producing only core but not extensively glycosylated mucins led to decreased ETEC colonization of the small intestine. Interestingly, secretion of the heat-labile toxin, LT, by ETEC increases Muc2 secretion, creating positive feedback and increasing colonization.

Extracellular Matrix and Connective Tissue

The extracellular matrix (ECM) is an interstitial substance present in all tissues and organs. Although its exact composition and properties vary depending on its location within the body, it is generally composed of fibrous proteins, such as fibronectin, collagens, laminins, and proteoglycans. The ECM is secreted by the cells it surrounds, including fibroblasts and osteoblasts, and is attached to them via ECM receptors, such as integrins and syndecans, which enables feedback between ECM properties and cell functions, including adhesion, migration, proliferation, and differentiation. The ECM is a key site of bacterial adhesion, and interactions between bacterial adhesins and ECM components are the most extensively characterized in adhesin biology. Adhesins that are not lectins, and recognize one or more ECM proteins by means of protein-protein, rather than protein-sugar interactions, are referred to as MSCRAMMs (microbial surface components recognizing adhesive matrix molecules). There are also many adhesins that classify as lectins, and recognize glycopeptides or glycans within ECM proteins and/or ECM proteoglycans. Glycan epitopes occurring on multiple ECM components may partially explain the multiligand binding specificities observed with some bacterial adhesins. This is the case with some Gram-negative adhesins belonging to the family of multivalent adhesion molecules (MAMs), such as the *E. coli* HS MAM YebT, which recognizes the ECM proteins laminin, fibronectin and collagen IV, among other ligands, via a shared 3-O-sulfogalactosyl moiety.

Fibrinogen (Fgn) is a glycoprotein found mostly in plasma, but also deposited as fibrin in the ECM, where it serves a role in scaffolding. The *S. epidermidis* protein SdrG is a cell wall anchored protein that binds the β chain of Fgn via a dock, lock and latch mechanism. SdrG consists of N-terminal N domains (N1–3) responsible for Fgn binding, and C-terminal serine aspartate repeat (Sdr) region. While the N1 repeat appears to be proteolytically cleaved in vivo, the N2 and N3 repeats, which each assume a DEvariant-IgG fold, bind the fibrinogen polypeptide chain and lock it in place with the C-terminal extension of N3, which assumes a β -strand conformation and extends towards the N2 subdomain where it acts like a latch by complementing one of the β -sheets in N1. The staphylococcal proteins Clumping factor (Clf) A and ClfB are similarly organized, as are the A regions of the multi-ligand MSCRAMMs FnbpA and B (see below), but differ in terms of the epitope they target on fibrinogen. ClfA, for example, interacts with the γ chain of Fgn by a dock, lock and latch mechanism, but also binds residues in the Fgn D domain at a distinct site located in N3. ClfA has been implicated as a major virulence factor in *S. aureus* infection models of septic arthritis and infective endocarditis.

Collagens are the main constituents of extracellular matrices and most abundant protein in mammals, with 28 types of collagen described to date and giving rise to matrices that vary widely in terms of their stiffness, from rigid structures, such as bone, to compliant structures, such as tendons. One of the best characterized collagen binding proteins is *S. aureus* CNA, which consists of a ligand binding N-terminal A region (IgG-like domains N1–3), followed by 1–3 N-terminal repeat motifs (B1–3) and a sorting signal. CNA binds collagen I using a variant of the dock, lock and latch mechanism called the “collagen hug,” whereby the N1 and

N2 domains are connected via a long loop and cooperate to wrap around and “hug” the rope-like structure of a collagen monomer, and the C-terminal extension of N2 forms a β -strand that complements one of the β -sheets in N1 and locks the bound collagen in place. CNA is required for *S. aureus* adhesion to cartilage and has been identified as a virulence factor in staphylococcal infections including arthritis, endocarditis, osteomyelitis, mastitis and keratitis. The repetitive B region functions as a spring, projecting the A region away from the cell surface and sustaining adhesion under high mechanical forces.

Fibronectin (Fn) is deposited in the form of fibrils and forms a key structural component of the ECM but also occurs as a soluble plasma protein. *S. aureus* expresses two structurally related fibronectin binding proteins, FnbpA and FnbpB. The C-terminal domain contains tandem repeats (FnBRs) that recognize the type I modules at the N-terminus of Fn via a tandem β -zipper mechanism. In their unbound state, FnBRs are intrinsically disordered, but bound to Fn, they form β -strands which extend the antiparallel β -sheets of adjacent Fn type I modules. The repetitive nature of both type I modules and FnBRs means this binding mechanism leads to a unique stabilized fold (the β -zipper) and exceptionally high binding affinities. This domain arrangement and mode of binding is also conserved in a range of other adhesins, including the streptococcal adhesins SfbII/F1, SfbII, Sof22, and F2, *Borrelia burgdorferi* Fn-BA and others. Binding of Fn by *S. aureus* FnBRs also allows the bacteria to interact with the $\alpha 5 \beta 1$ integrin, which initiates bacterial invasion of host cells. Recent work on the interaction of *S. gordonii* adhesin CshA with Fn revealed a two-state catch-clamp binding mechanism distinct to the β -zipper. Fn binding is associated with two regions (NR1 and NR2) localized in the nonrepetitive CshA N-terminal domain. NR1 is an intrinsically unstructured region and its interaction with Fn is highly dynamic, while NR2 is a discrete Fn-binding domain with a lectin-like fold and high affinity for Fn, suggesting a bipartite, cooperative mechanism involving a low affinity but high capture radius domain (catch) and a high affinity interaction with a carbohydrate binding domain (clamp). The N-terminal A region of Fnbps contains three independently folded N domains (N1–3) with divergent binding specificity depending on protein variant and strain, but all also bind fibrinogen via a dock, lock and latch mechanism. This organization and mechanism of fibrinogen binding is shared with the *S. aureus* clumping factor A (ClfA). In contrast to ClfA, Fnbp N domains can also bind elastin, which is important for connective tissue colonization, and can capture plasminogen from plasma, which plays an important role in the formation of bacteria-containing clumps and endocarditis.

MAM7 is found on the surface of many bacterial pathogens. It has been identified as a bacterial adhesion molecule that binds two ligands, fibronectin and phosphatidic acid. Using microbial genetics and various infection models, this outer membrane receptor has been shown to contribute to virulence for many Gram-negative bacteria. Further studies using a recombinant form of MAM7, demonstrated that MAM7 can be used as an antimicrobial by attenuating the binding and colonization of pathogens, including MRSA, as they also use fibronectin for adhesion. In a recent study, it was shown that the MAM7 treatment could attenuate infections by *Pseudomonas aeruginosa* in a burn model without affecting vascularization or promoting an inflammatory response. Furthermore, a molecule with intermediate binding, such as MAM7, does not affect wound healing, whereas antimicrobials that bind with a much higher affinity to fibronectin, have a detrimental effect on wound healing.

Laminins are high molecular weight (400–900 kDa) heterotrimeric proteins consisting of cross-linked α -, β -, and γ -chains forming a cross-like structure. They can assemble into higher-order sheet like structures and cross-link the ECM. Several laminin binding adhesins have been identified, including the *Haemophilus influenzae* autotransporter adhesin Hap, the EHEC autotransporter EhaB, and the leptospiral proteins OmpL47, Lsa24, Lsa27 and Lsa63. However, structural and mechanistic details of these interactions remain to be determined.

Elastin is a fibrous protein found in connective tissues, and forms a cross-linked highly elastic matrix than can be stretched to several times its length but recoils upon force relaxation. Several *S. aureus* proteins, including Fnbps, bind elastin, but *S. aureus* also expresses a separate elastin binding protein, EbpS, which binds both soluble elastin and insoluble fibrous elastin (tropoelastin) via its N-terminal domain. The leptospira IgG-like protein B (LigB) also binds elastin, which likely facilitates adherence to fibroblasts and lung infection. However, structural details regarding the mechanism of elastin binding by adhesins have yet to be uncovered.

Endothelial Cells

The endothelium forms the inner lining of the vascular system, including blood vessels and the heart, and lymphatic vessels. They also form a part of the blood-brain barrier and protect the central nervous system from invading pathogens. Bacteria have evolved many ways to interact with the endothelial cell surface, allowing them to modulate vascular clotting and to reach and persist in the central nervous system, including the brain, blood and lymphatic vessels, niches typically inaccessible to microbes.

S. aureus and Streptococcus species can cause vascular infections, including endocarditis and sepsis, and many receptors are involved in causing these diseases, including circulating ECM proteins that act in strengthening bacterial–endothelial adhesion and platelet receptors important for bacteria induced clotting, discussed elsewhere in this chapter. The interactions they form to specifically mediate endothelial adherence are described here. *S. aureus*'s ability to bind Fn, thereby engaging the $\alpha 5 \beta 1$ integrin, not only allows it to invade cells but also triggers pro-inflammatory responses in endothelial cells and positive feedback by upregulating $\alpha 5 \beta 1$ integrin expression on the endothelium in turn. Adhesion-promoting pro-inflammatory responses are triggered to recruit phagocytes and activate epithelial migration as part of normal wound healing, making wounded tissues susceptible to colonization. Vascular damage as a result of infection and inflammation also leads to exposure of collagen, which is readily exploited by both Staphylococcus and Streptococcus as an adhesion substrate and further increases bacterial attachment to the endothelium. Adhesins such as the *S. aureus* extracellular adhesion protein (Eap) of the SERAM (secretable extended

repertoire adhesion molecule) family exploit the inflammation triggered upregulation of the intercellular adhesion molecule (ICAM)-1 on endothelial cells by competitively blocking the adhesion to and transmigration of phagocytes through the endothelium.

CEACAMs (carcinoembryonic antigen-related cell adhesion molecules) are expressed by endothelial and phagocytic cells and involved in cell-cell adhesion. They are exploited by several pathogens including *Neisseria* species, which can cause vascular infections and meningitis by crossing the blood-brain barrier. *Neisseria* species express opacity associated (Opa) proteins, which interact with CEACAMs with nanomolar affinity, outcompeting their native interactions involved in cell-cell adhesion and triggering bacterial invasion. Opa-mediated binding to CEACAMs triggers increased CD105 (endogline) expression and activation of $\beta 1$ integrin, which increases host cell adhesion and inhibits infection-induced cell shedding. The platelet endothelial cell adhesion molecule (PECAM)-1 is expressed by endothelial and phagocytic cells as well as platelets, and it is involved in phagocyte transmigration, angiogenesis and integrin activation. PECAM-1 is also recognized by *Streptococcal* pili, via the adhesive protein RrgA. RrgA colocalizes with its receptor PECAM-1 at the blood-brain barrier endothelium and is required for bacterial entry into the brain and development of meningitis as a result of bacteremia. Interestingly, PECAM-1 expression is downregulated following bacterial adhesion, leading to loss of PECAM-1 from intercellular junctions, increased intercellular gap formation and enhanced permeability of endothelial barriers.

Borrelia burgdorferi, a spirochete and causative agent of Lyme disease, expresses several adhesins, including DbpA and B, which both bind to glycosaminoglycans, and BBK32. BBK32 recruits soluble fibronectin via its N-terminal region and undergoes binding-induced folding into a tandem β -zipper, similar to *S. aureus* Fnbps. Under vascular shear stresses, recruited Fn extends but binds BBK32 more tightly via a catch-bond mechanism. The transfer of mechanical load along a series of Fn-BBK32 complexes on the bacterial surface allows the spirochete to maintain adherence to the vessel wall under fluid shear, as well as movement along the vasculature and extravasation.

Nerve Cells

Although bacterial infections of the peripheral nervous system are relatively rare, they are associated with high morbidity and mortality. *Mycobacterium leprae*, the causative agent of leprosy, is able to adhere to many tissues, including endothelium, macrophages, dendritic cells and myelinating Schwann cells, which wrap around and form the myelin sheath protecting the axons of motor and sensory neurons. The attachment to and invasion of Schwann cells by *M. leprae* triggers demyelination, resulting in sensory motor loss and long-term disability. Adhesion to Schwann cells was long thought to be mediated by alpha-dystroglycan and ErbB-2. Both were later shown to be associated with 9-O-acetyl GD3 ganglioside, the real host receptor which is recognized by glycolipid-I on the surface of *M. leprae*. The protein Hlp binds laminin as well as the glucosaminoglycans heparin and heparin sulfate and also contributes to Schwann cell adhesion. Attachment of *M. leprae* leads to increased expression of 9-O-acetyl GD3, activation of the neuregulin receptors, ErbB-2 and ERK 1/2, cell proliferation, demyelination and nerve damage. Demyelination also allows *M. leprae* to invade Schwann cells, which is necessary for proliferation and persistence of this obligate intracellular pathogen. Spirochetes such as *Borrelia burgdorferi* and *B. garinii* can also colonize glial cells and cause neuropathies. The host receptor galactocerebroside (GalCer) has been implicated in *Borrelia* adhesion via its interaction with the bacterial surface protein OspA. The sialogangliosides GD1a and GT1b and acidic glucosaminoglycans have also been identified as *Borrelia* receptors, but do not rely on OspA for binding. Adhesion to the nerve fiber modulates the amplitude and conduction velocity of the action potential, likely due to adhesion-triggered desorption of myelin bound calcium rather than demyelination.

Bacterial Adherence to Blood Cells

Blood cells include red blood cells (erythrocytes), white blood cells (platelets) and immune cells such as neutrophils, macrophages, microglial cells, dendritic cells, T and B cells. Erythrocytes are a popular system to study bacterial adhesins in hemagglutination assays and have been used in this capacity for over hundred years, little is known about their specific role in bacterial adhesion in vivo. In contrast, platelets and immune cells have been described as specific targets of bacterial adhesion and thus we will focus on these two cell types below.

Platelets

Despite their structural simplicity compared to other cells, platelets play important functions during infection, especially in infectious endocarditis as a result of bacterial infections in the oral cavity (e.g., *Streptococcus gordonii*, *Streptococcus sanguinis*, *Porphyromonas gingivalis*) and sepsis (e.g., through *S. aureus* blood-stream infection). There is a clear link between bacterial adhesion to platelets and prothrombic activation, but they are also discussed as part of the innate immune response since bacterial adhesion can trigger antimicrobial peptide secretion and enhance the activity of neutrophils and neutrophil extracellular trap (NET) formation.

Platelets carry a number of adhesin receptors on their surface, including the hemostatic integrins GPIIb α and GPIIb-III α , Toll-like receptors, complement receptors and the immunoglobulin (Ig) G receptor Fc γ RII. Bacterial adhesion to platelets occurs either via

direct interaction between adhesins and surface receptors, or indirectly via binding of adhesins to circulating plasma proteins, such as von Willebrand factor (vWF), fibronectin, or fibrinogen, which in turn are ligands of platelet receptors. The leucine-rich repeat containing glycoprotein GPIb α is an integrin involved in hemostasis and is usually involved in binding shear-activated von Willebrand Factor (vWF) to induce aggregation. Streptococcus directly binds GPIb α via highly glycosylated serine-rich repeat (SRR) proteins such as SrpA, GspB, SspA/B and the hemagglutinin salivary antigen, Has. Homologous SRRs, such as the GspB homolog SrpA, are found in *S. aureus*, and disruption of SRR adhesin- GPIb α interactions has been shown to inhibit platelet aggregation and protect from infective endocarditis in vivo. Structural and functional studies have shown direct adhesion is mediated by the interaction of Siglec-like domains of SRRs with sialoglycan modifications in GPIb α . Interestingly, *S. oralis* has evolved a sialoglycan-independent SRR, Fap1, which mediates platelet adhesion, and produces neuraminidase to inhibit SRR-mediated adhesion of other Streptococcal species. Other adhesins bind to soluble vWF, which when bound to bacteria, does not require shear force as an activator to induce binding to GPIb α and aggregation. The glycoprotein GPIIb-III α is also an integrin involved in hemostasis, and a receptor for both direct bacterial adhesion and indirect adhesion, mediated by adhesin binding to circulating fibronectin and fibrinogen. Several bacterial MSCRAMMs, including *Staphylococcus aureus* clumping factors ClfA and ClfB and fibronectin binding proteins FnbpA and FnbpB, as well as Streptococcus M1, bind to GPIIb-III α via such indirect interactions. The *Staphylococcus epidermidis* serine-aspartate repeat (Sdr) protein SdrG binds IIB-III α both indirectly via fibrinogen and directly. The *S. aureus* iron-regulated surface determinant (Isd) proteins usually scavenge heme iron, but can also directly bind GPIIb-III α in the absence of plasma proteins, as can the *Streptococcus gordonii* platelet adherence protein PadA. Binding sites for directly bound adhesins overlap those required for fibrinogen binding. Bacterial adhesion via GPIIb-III α induces outside-in platelet signaling via the cyclooxygenase and Tx pathways, which leads to prothrombotic activation and platelet aggregation observed in infectious endocarditis.

The immune receptor Fc γ RII recognizes the Fc domain of IgG, and bacteria bound by IgG can interact with platelets. Bacterial adhesion to Fc γ RII can cause cross-talk with GPIIb-III α and outside-in signaling involved in prothrombotic platelet activation. In the case of *S. aureus* and *P. gingivalis*, bacterial adhesion to platelets via Fc γ RII leads to bacterial internalization, but little is known about the role of this during infections. While some view bacterial internalization by platelets as an escape-route into a replicative niche, others view platelets as a part of antibacterial innate immunity. Although platelets do not form phagolysosomes, it is thought that endosomes containing internalized bacteria fuse with α -granules, leading to bacterial clearance.

Immune Cells

Innate immune cells including neutrophils, macrophages and dendritic cells form the first line of defense against bacterial infections. They display a wide range of receptors involved in recognition and binding of pathogens, including toll-like receptors (TLRs), Fc receptors, lectins, scavenger receptors, and integrins. However, many bacterial pathogens adhere to these receptors in a way that allows them to subvert immune cell signaling, either to block phagocytic function and antibody production, or to use them as a protective niche for proliferation, persistence, and dissemination to distal colonization sites.

Yersinia species are well adapted to evade immune cell mediated clearance, allowing them to colonize lymphoid tissues. During infection of the human host, enteropathogenic *Yersinia* express two major adhesins, invasin and YadA, which are both implicated in adhesion to and invasion of epithelial and phagocytic cells, contributing to serum resistance. *Yersinia* also express several minor adhesins, including Ail, pH 6, and Pla, some of which are cryptic but play important roles in immune cell subversion in the absence of one or both major adhesins. Invasin is an autotransporter adhesin expressed during the initial contact with the host, and has a modular architecture consisting of an N-terminal OM embedded β -barrel domain and periplasmic α -domains, and an extracellular Ig-like (BIG) domains (D1–4) capped by a lectin-like head domain (D5). D4 and D5 form a functional module that binds β 1 integrins with approximately 100 times higher affinity than Fn. While this facilitates bacterial attachment and, given a high enough concentration of invasion-integrin complexes, a zipper-like invasion mechanisms, the invasin β 1 interaction serves additional functions. Engagement of β 1 on neutrophils, for example, triggers PI3K activation, production of reactive oxygen species, and release of chromatin, highlighting invasin's contribution to neutrophil extracellular trap formation. The trimeric autotransporter adhesin *Yersinia* adhesin A (YadA) and its interactions with macrophages are among the best studied in the field. YadA is composed of an N-terminal passenger domain and a C-terminal translocation domain. The N-terminus contains a distal β -roll head region that is connected to the translocation domain via a central coiled-coil stalk region. Three YadA C-termini contribute to form a 12-stranded β -barrel, which inserts into the outer membrane and exposes the passenger domain on the extracellular face of the membrane. YadA is essential for *Yersinia enterocolitica*, and YadA-deficient bacteria are avirulent in rodent infection models. YadA mediates adherence to many tissues via ECM proteins, and in the absence of tight attachment via YadA, T3SS effectors are not efficiently translocated into host cells. It also interacts with integrins via an ECM bridge, allowing it to invade immune cells. Beyond that, YadA contributes to serum resistance by adhering to the bacterial cell surface via complement factor H, which acts as a negative regulator of the alternative pathway and counteracts deposition of C9, a component of the terminal lytic complex. YadA also recruits C4 binding protein, a negative regulator of both classical and lectin pathways of complement recruitment.

Infective endocarditis caused by oral streptococci is thought to depend on interactions between streptococci via sialic acid-binding SRR adhesins and monocytes. Attachment of the *S. gordonii* adhesin Hsa to human monocytes depends on sialylation and leads to an up-regulation of the dendritic cell markers CD83, CD1a, CD86 and interleukin-12, causing differentiation into mature dendritic cells. Attachment of SRRs to monocyte-derived dendritic cells is also required for their full activation, which contributes to

disease development. The periodontal pathogen *Porphyromonas gingivalis* attaches to complement receptor-3 (CR3) via its type-1 fimbriae. Binding of the tip adhesin FimE stimulates TLR2 inside-out signaling, which induces conformational changes in CR3 leading to monocyte adhesion to the endothelium and extravasation. The proadhesive conformation of CR3 also leads to cellular invasion by *P. gingivalis* and avoidance of phagolysosomal degradation.

Targeting Adhesion to Prevent Infection

As the above-mentioned examples highlight, the surface structures, host receptors and mechanisms underpinning bacterial adhesion appear incredibly diverse, but also, in many cases, appear redundant. So, is it possible to interfere with bacterial infection by targeting adhesion? Many approaches to achieve this are currently under investigation and development. Some, particularly vaccines and therapeutic antibodies targeting adhesins, are undergoing clinical trials and show great promise as future supplements or alternatives to antibiotics in the face of rising drug-resistance. For a more comprehensive summary of current approaches we refer the reader to our recent review of antiadhesion therapy.

Targeting adhesion as a defense strategy is, however, not a human invention. Many naturally occurring molecules have antiadhesive properties associated with innate immunity against bacterial infections. A prominent example are human milk oligosaccharides and glycoconjugates, which exert a protective function against infantile diarrheal diseases through binding and neutralizing bacterial adhesins by acting as receptor decoys. Another group of human defense molecules with antiadhesive properties are collectins. While they have far-reaching activities in immunoregulation and disease modulation, they also directly impede colonization by neutralizing adhesive carbohydrates on pathogens or tissue surfaces. The surfactant protein A (SP-A), for example, is an abundantly expressed collectin that binds both UPEC and the UPEC FimH receptor uropilin 1a in the bladder. In the absence of SP-A, host susceptibility to bladder infections is increased. There are many more naturally occurring adhesion inhibitors, including in plant-derived foods, and characterizing and harnessing these often highly complex mixtures may allow us to treat infections more effectively.

By leveraging our knowledge of adhesion structures and mechanisms it is also possible to purposefully design and produce compounds that target either a broad range or specific subset of adhesive microbes (Fig. 1). The detailed structural and functional characterization of FimH-carbohydrate interactions, for example, has led to the development of synthetic mannosides which target host colonization by fimbriated *E. coli* with high efficacy and specificity and good bioavailability. Oral administration of antibodies targeting fimbrial adhesins of ETEC has proven effective in the prevention of diarrheal disease, providing the first clinical evidence that fimbrial adhesins function as protective antigens. In addition to compounds neutralizing adhesins on the bacterial surface, compounds blocking adherence by protecting host receptors are also under investigation. For example, treatment of burn wounds with a bacteriomimetic material (MAM7) that targets fibronectin and phosphatidic acid receptors on the exposed tissue has been shown to decrease bacterial burden. Since many microbes adhere via glycosphingolipids exposed on the host cell surface, the use of GSL inhibitors to deplete these receptors from host tissues, which has been used as a last resort to treat systemic infections and osteomyelitis in patients, has led to complete convalescence. Targeting virulence rather than survival could reduce evolution of drug resistance pathogens to these applications. Although so far there are only a few examples of adhesion inhibitors undergoing clinical trials or allowed for clinical use as a last resort, the above studies highlight that this is a worthwhile area for further discovery and development, which may eventually replenish our arsenal to fight drug-resistant infections.

Fig. 1 An overview of strategies used to prevent bacterial adhesion to host cells. (A) In the absence of inhibitor, bacteria (green) employ surface localized adhesins to engage receptors on the host cell surface (blue). (B) Inhibition of biogenesis or surface display of nonessential host receptors prevents bacterial attachment, for example the use of glycosphingolipid inhibitors has been used as a strategy of last resort to treat systemic infections. (C) Host-derived or artificial molecules that bind to host receptors with high affinity competitively inhibit the binding of bacterial adhesins that share the same receptor. For example, materials based on MAM7 fragments competitively block adhesion of MAM7-expressing bacteria to host tissues. (D) Host-derived or exogenous molecules that act as host receptor decoys bind to bacterial adhesins, thereby interfering with efficient attachment to the host cell surface. For example, mannosides bind to the fimbrial adhesin FimH with high affinity, a strategy used to prevent UPEC attachment and urinary tract infections. (E) Host-synthesized or exogenous antibodies targeting bacterial adhesins can block interactions between adhesin and host receptor either through steric hindrance, or by preventing a conformational change in the adhesin necessary for high affinity binding to the host receptor.

Glossary

ART (anti-retroviral therapy) Broadly defined, these include any medications active against HIV. In practice, ART usually refers to a combination of a protease inhibitor and two reverse transcriptase inhibitors that have powerful inhibitor effects against HIV replication. Also known as highly active anti-retroviral therapy (HAART).

HIV (human immunodeficiency virus) An RNA retrovirus, related to a series of simian immunodeficiency viruses, which is the cause of AIDS.

opportunistic infections Infections that do not cause significant disease in nonimmunocompromised hosts, but can cause severe disease in people with AIDS; for example, Kaposi's sarcoma (KS) and pneumocystis carinii pneumonia (PCP).

stigmatization The process by which the stigma attached to certain behaviors, notably homosexuality and intravenous drug use, is transferred to a disease, such as AIDS, having a substantial impact on theories of, and responses to, the disease.

viral load A measure of the concentration of HIV RNA in a person's blood. It can be used to screen patients for HIV and to monitor the progress of therapy.

Abbreviations

3TC	Lamivudine
ACT UP	AIDS Coalition to Unleash Power
AIDS	Acquired immune deficiency syndrome
ART	anti-retroviral therapy
AZT	azidothymidine
CDC	Centers for Disease Control and Prevention
CMV	cytomegalovirus
ELISA	enzyme-linked immunosorbent assay
HPA-23	Heteropolyanion-23
HAART	highly active anti-retroviral therapy
HIV	human immunodeficiency virus
HTLV-III	human T-lymphotropic virus type III
IDUs	intravenous drug users
KS	Kaposi's sarcoma
LAV	lymphadenopathy virus
PCP	pneumocystis carinii pneumonia
PCR	polymerase chain reaction
PEPFAR	President's Emergency Plan for AIDS Relief
SIV	simian immunodeficiency virus
STDs	sexually transmitted diseases

Defining Statement

The appearance and rapid globalization of the AIDS pandemic demonstrate the social and economic processes that shape the distribution of diseases at present. These same processes also determine access to life-saving treatment which, as of yet, has reached only a minority of people who would benefit from it.

This article is a reprint of D.S. Jones, A.M. Brandt, AIDS, Historical, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 1–16.

Introduction

Acquired immune deficiency syndrome (AIDS), first identified in 1981 is an infectious disease caused by the human immunodeficiency virus (HIV). The virus attacks the host's immune system, causing its eventual failure. This failure leaves affected individuals vulnerable to many infections and cancers, leading inexorably to severe morbidity and high mortality. HIV emerged in the middle of the twentieth century, following the infection of humans with simian immunodeficiency viruses (SIV). Spread sexually and through blood, it penetrated populations in Africa, Europe, and the United States in the 1970s. AIDS appeared in the 1980s caused considerable fear and provoked dramatic social responses. Despite rapid progress in scientific understanding and medical treatment of the disease, and despite the existence of valuable preventive technologies, HIV continued to spread rapidly throughout the world in the 1980s and 1990s. Decisive treatments appeared in the late 1990s, triggering debates about whether or not these could be implemented on a global scale. Although dramatic progress has been made, disparities in risk of infection and in access to treatment continue to expose critical inequities in the distribution of social and medical resources in developed and developing countries.

Pathophysiology of HIV and AIDS

HIV is an RNA retrovirus with fewer than 10 000 bp. These code for three structural genes and six regulatory genes that are, in turn, transcribed and spliced in a variety of ways to produce a total of 15 proteins. The viral particles, or virions, have an icosahedral structure. Two identical strands of RNA and the virus's crucial proteins – protease, integrase, and reverse transcriptase – are enclosed within a bullet-shaped core, composed of the capsid protein (p24). This, in turn, is surrounded by the viral envelope, composed of an inner layer, made up of the matrix protein (p17), and an outer lipid layer. Seventy-two spikes, made up of proteins gp120 and gp41, protrude from this envelope. The virus can attack any cell that expresses the CD4 molecule and a coreceptor, often the chemokine receptors CCR5 or CXCR4. The virus's gp120 proteins bind to CD4, allowing the viral envelope to fuse with the cell membrane, releasing the core into the cell's cytoplasm. Once there, viral reverse transcriptase translates the viral RNA into DNA. This viral DNA is then inserted, by viral integrase, into the genome of the infected cell. The cell's own machinery then transcribes and translates the viral DNA, producing a single long protein. This is cleaved, by the viral protease, into the 15 proteins. New virions form and bud from the infected cell. A chronically infected person can produce more than 10 000 000 000 virions each day.

HIV primarily targets the CD4+ subset of T lymphocytes, known as the helper T cells, which regulate crucial aspects of the normal immune response. But any cell that expresses CD4 can be infected. Infection has been reported in macrophage, epithelial cells in the gastrointestinal and urinary tracts, astrocytes, microglial cells, cardiac myocytes, and a variety of other cell types. Infected individuals can transmit infection through blood, semen, and other genital secretions. Heterosexual transmission is responsible for most of the infections worldwide, possibly as many as 85%. However, substantial transmission has also occurred through maternal-fetal infection (during pregnancy, birth, or breast-feeding), homosexual contact, needle-sharing by intravenous drug users (IDUs), and contaminated blood products. Transmission has also been reported through organ donation, renal dialysis, artificial insemination, and acupuncture. HIV cannot be transmitted by insect bites, and it is almost never transmitted through casual contacts at home or in public.

The predominant mode of transmission varies substantially from country to country. In sub-Saharan Africa, most cases have occurred from heterosexual contact. In the United States, in contrast, roughly 45% of the cases have occurred among men who have sex with men, 25% among IDUs, and just over 10% among heterosexuals. Meanwhile, in India, transmission through drug use predominates in the northeastern states, while heterosexual transmission is most common in the south. Since modes of transmission vary so widely from place to place, public health campaigns to prevent transmission must be targeted to reflect local circumstances.

When HIV enters a body, initial infection and replication produce a surge in viral load in the victim's blood (viremia). The viremia triggers a vigorous immune response: antibodies are generated, especially against p24 and gp41, and the infection is initially contained, largely within the body's lymphoid tissues. This first stage of infection often goes unnoticed, though some individuals do experience a flulike prodromal syndrome characterized by fever, rash, and malaise. After this initial stage, an individual may remain free of symptoms for many years. During this time, the virus continues to attack the immune system, causing rapid turnover of CD4+ lymphocytes. In most people, the virus eventually gains the upper hand: the CD4+ count slowly but steadily declines and immune functions become increasingly compromised. This latent period, in which infected individuals are generally healthy, typically lasts for 10 years. Other outcomes are also possible. In roughly 10% of people, for instance those with mutations to CCR5, the immune system contains the virus and there is no progressive loss of immune function. These people have remained disease free for as long as 20 years after infection. In other individuals, especially in the setting of malnutrition and tuberculosis, the progression from infection to AIDS to death occurs within 1 year.

In the majority of cases, HIV eventually cripples the host's immune system, leaving the infected individual vulnerable to other disease-causing agents in the environment. Clinical signs of infection generally begin to appear when the person's CD4+ count, normally around 1000 cells ml⁻¹, drops below 500. As the immune system deteriorates further, a series of opportunistic infections begin to appear, including thrush, tuberculosis, pneumocystis carinii, histoplasmosis, toxoplasmosis, herpes, cytomegalovirus (CMV), and *Mycobacterium avium* complex. According to the current criteria, established in 1993, the diagnosis of AIDS is given to patients who are HIV+ when either their CD4+ count drops below 200 or they develop opportunistic infections or cancers (especially Kaposi's sarcoma (KS)), AIDS encephalitis, or AIDS wasting syndrome. Clinical presentations of AIDS have varied over the course of the epidemic and in different countries. In the United States, the first cases presented with pneumocystis carinii pneumonia (PCP) or KS. In sub-Saharan African countries, a syndrome of chronic diarrhea and severe weight loss ('Slim disease')

was common; many people also presented with fulminant tuberculosis. Now that anti-retroviral therapy (ART) controls many HIV infections in the United States, patients often have greater problems with medication side effects than with opportunistic infections.

HIV is accepted as the causative agent of AIDS by an overwhelming majority of physicians, scientists, and public health experts. Despite this, opposition to the HIV explanation appeared early in the epidemic and has persisted in a vocal minority. Citing the existence of clinical syndromes that resembled AIDS in HIV individuals (known as idiopathic CD4⁺ lymphocytopenia), some observers have argued that HIV is an insufficient explanation for AIDS. One theory argued that HIV and other factors together trigger an autoimmune response that produces immunodeficiency. Another replaced the infection model with a pollution model: recreational drug use, overuse of antibiotics, multiple sexually transmitted infections, exposure to impure blood products, and malnutrition somehow converged to produce AIDS. The most prominent skeptic of HIV has been South African President Thabo Mbeki, who long refused to acknowledge HIV as the cause of AIDS. His advocacy of alternative theories proved to be a major obstacle to the implementation of ART in South Africa in the early 2000s.

Origins and Spread of HIV

HIV was first isolated in January 1983 by Francis Barre-Sinoussi and Luc Montagnier at the Pasteur Institute in Paris. They named it lymphadenopathy virus (LAV) and suspected that it might be the cause of AIDS. In April 1984 Robert Gallo and his team at the National Institutes of Health announced the discovery of another virus that they believed to be the cause of AIDS. Recognizing the virus as a retrovirus, related to two retroviruses that Gallo had previously shown to cause lymphoma, they named it human T-lymphotropic virus type III (HTLV-III). A third group, led by Jay Levy at the University of California at San Francisco, independently isolated the virus as well. After a bitter priority dispute between Montagnier and Gallo, researchers realized that LAV and HTLV-III were the same virus. In 1986 an international commission officially assigned the name HIV.

Subsequent study revealed that many different strains of HIV circulate in human populations. In 1985 a second virus, now named HIV-2, was identified in some cases of AIDS in West Africa. In 1994 two subgroups of HIV-1 were described: HIV-1 group M (main) and HIV-1 group O (outlier). In 1998 a third subgroup was described, HIV-1 group N (non-M/non-O, or new) in two individuals in Cameroon. HIV-1 M counts for the vast majority – over 90% – of all cases of AIDS. Many subtypes of HIV-1 M now exist, which vary in their geographic distribution. While subtype B dominates in the Americas and western Europe, A and B can be found in eastern Europe, B and C in North Africa and East Asia, and A, D, F, G, C, H, J, K, and others in sub-Saharan Africa. Analysis of these subtypes has shown that a single individual can become infected with multiple subtypes and that these can recombine to produce novel forms of the virus.

Careful analysis of viral genetics and host phylogeny has revealed the origins of the different subgroups of HIV. The family of retroviruses has two main divisions. The first division, the oncoviruses, had been described in animals early in the twentieth century; Gallo described the first human oncogenic retrovirus in 1980, HTLV-1. HIV belongs to the second division, the lentiviruses, which are cytopathic. They have been found in a variety of animal species, including horses, goats, humans, and other primates. The various strains of SIV are the closest relatives of HIV. The first SIV was identified in 1985 in a rhesus monkey, in captivity, which suffered from an AIDS-like illness. Subsequent study has found over 20 species-specific strains of SIV. Recombination between these lineages obscures the details of their phylogeny. However, genetic analysis of the strains suggests a common origin, in Africa, in the Pleistocene epoch. Each species-specific strain is harmless in its natural host, a fact consistent with the ancient association between the strains and their hosts. But when a strain infects an individual from another species, an AIDS-like illness results. For instance, the rhesus monkey from which SIV was first identified was infected with a strain from a sooty mangabey.

HIV reflects a similar phenomenon. At some point in the past, a single subspecies of chimpanzee, *Pan troglodytes troglodytes*, was infected with two different strains of SIV, one from red capped mangabeys, and one from spot nosed monkeys. These two strains recombined in chimpanzees to form a novel strain, SIVcpz. This strain then jumped to humans and evolved into HIV-1 M. When and where did this jump take place? Chimpanzees infected with SIVcpz have been found in Cameroon, Gabon, Congo, Central African Republic, and Equatorial Guinea, an area that corresponds well with the epicenter of the human epidemic. Transmission from chimpanzees to humans likely occurred repeatedly, wherever humans hunted chimpanzees for food. The three different subgroups of HIV-1 (M, N, O), for instance, represent infections of humans with three different strains of SIVcpz. HIV-2, in contrast, came from strain of SIV found in sooty mangabeys in West Africa, where the monkeys are hunted and kept as household pets. Some researchers argue that humans were infected hundreds or thousands of years ago. Most, however, believe that HIV first emerged in the 1930s or 1940s.

Many theories have been offered to explain why significant spread of HIV among humans began at this time. During the final decades of French colonial rule in Africa, policies of resettlement, forced labor, and urbanization destabilized African populations. Malnourished and overworked, some people turned to chimpanzees as a food source. This increasingly brought SIV into contact with human populations who had reduced resistance to infection. This foothold may have facilitated the evolution of SIV into HIV. Once human-to-human transmission became possible, HIV spread during the turbulent social changes that followed decolonization after World War II. Civil wars produced migrations of refugees. Urbanization disrupted traditional social practices, marginalized women, and promoted prostitution. Governments increased spending on military programs and sacrificed social services and education. Poorly funded health care programs had to reuse needles, something that accelerated the spread of HIV. Major vaccination campaigns in the 1950s and 1960s might have played a crucial role. Highway construction and improving transportation allowed the virus to spread from its central African origins throughout sub-Saharan Africa, and then throughout the world. International aid workers and tourists who indulged in commercial sex industries became infected and brought the virus back to

their home countries. Once HIV gained access to developed countries, it found many routes of spread. Needle sharing spread HIV among IDUs in New York City in the 1970s. The 1970s also saw the emergence of gay identity, especially in San Francisco where, for some gay men, promiscuous anonymous sex became an important part of their identity. Blood sharing technologies, particularly transfusion and fractionated blood products, had also become more widespread. These varied factors transformed a local practice – hunting of chimpanzees for food – into a global pandemic. This rapid evolution of HIV over several decades may be a harbinger of further changes yet to come.

Researchers have scrutinized medical records to detect HIV or make retrospective diagnoses of AIDS to reconstruct a detailed prehistory of the epidemic. Collections of old blood samples have been tested to find direct evidence of the presence of HIV in human populations. The oldest match comes from a 1959 sample from Leopoldville (Kinshasa), Congo. This strain is the common ancestor of three of the current subtypes of HIV-1 M. The earliest definitive clinical evidence of AIDS comes, surprisingly, from a Norwegian family. In 1961 a Norwegian teenager worked on a merchant ship that sailed down the west coast of Africa, stopping in many ports from Senegal to Cameroon. During this trip, he was treated for gonorrhea. He subsequently returned to Norway and began to show symptoms of AIDS in 1966. His wife fell ill in 1967 and their daughter, born that year, became sick in 1969. All three died in 1976. Subsequent testing of blood samples taken from them between 1971 and 1973 have tested positive for HIV-1 O, a subgroup found most often in Cameroon. The earliest case in the United States has been identified in a 15-year old from St. Louis. Diagnosed with a severe chlamydial infection in 1968, he died in 1969. Autopsy revealed extensive, aggressive KS. Tests on surviving blood samples, performed in 1987, confirmed the diagnosis of HIV. Dozens of other likely cases of AIDS, that lack confirmatory blood tests, have been found in Africa, Europe, and the United States in the 1970s. How prevalent was the infection? Screening of surviving blood samples has revealed its insidious spread. Samples from sub-Saharan Africa show a prevalence of 0.1% in 1959, 0.3% in 1970, and 3% in 1980. Data from clinics for IDUs in New York City show that HIV had entered the city by 1976. Infection had reached 9% of IDUs by 1978, 39% by 1980, and over 50% by 1984. These data suggest that HIV existed, but was rare, in human populations in the 1950s. By the 1970s, however, parallel epidemics had begun in sub-Saharan Africa, the United States, and Europe.

Emergence and Recognition of AIDS

In the late 1970s, physicians in New York and California noted the increasing occurrence of KS, PCP, and other rare infections among previously healthy young men. Because of the unusual nature of these diseases, which are typically associated with a failure of the immune system, epidemiologists began to search for characteristics that might link the cases. In the summer of 1981, Michael Gottlieb described an outbreak of PCP among five homosexual men in Los Angeles. By the end of the year, similar cases, as well as unusual cases of KS, had been described among homosexuals, IDUs, and female sexual partners of IDUs, in Los Angeles, San Francisco, New York City, and Europe. Researchers traced these opportunistic infections to a specific deficit in CD4+ cells. Although several risk groups had been identified, etiological hypotheses focused on particular aspects of gay culture which might explain the outbreak of the disease, including use of amyl nitrite ('poppers') and steroid skin creams, antigen overload, and pathogenic sperm. Some researchers suggested a link to CMV.

Other risk groups were identified in 1982. Researchers traced cases of immunodeficiency and opportunistic infections to contaminated blood products, especially the clotting factors used to treat hemophilia. Although the risk posed by clotting factor concentrates was soon recognized, many people with hemophilia, tragically, had no choice but to continue taking them. Meanwhile, during the summer of 1982, deaths from opportunistic infections, notably toxoplasmosis, were described among Haitians at detention camps in Florida. The occurrence of cases in diverse risk groups suggested infection with a bloodborne agent. In September 1982, the Centers for Disease Control and Prevention (CDC) replaced the range of early labels (gay plague, gay cancer, and gay-related immune deficiency) with a more neutral term: AIDS. By the end of the year, over 1000 cases had been described.

By early 1983, the CDC had defined AIDS as the result of infection with an unknown transmissible agent, characterized its mode of transmission, and defined four risk groups, the '4H Club': homosexuals, heroin addicts, hemophiliacs, and Haitians. Recognizing that many European cases had links to Africa, researchers speculated that Africa might be the source of the virus. This suspicion was strengthened by reports of slim disease and KS beginning to emerge from Uganda, Zaire, and Zambia. The identification of HIV by Barre-Sinoussi, Montagnier, and Gallo enabled intensive scientific scrutiny of the epidemic. The fortuitous emergence of HIV at exactly the moment when scientists had developed the techniques needed to study it allowed rapid progress in understanding the biology and pathophysiology of the virus. The problems posed by the virus – biologically, clinically, and epidemiologically – quickly moved virology and molecular immunology onto the center stage of scientific research. The first crucial innovation came in March 1985 with the licensing of the first blood screening tests. The enzyme-linked immunosorbent assay (ELISA) and the Western Blot did not detect the virus itself. Instead, both identified the high levels of antibody produced by most infected individuals within several months of infection. Although the tests could miss people who had recently been infected, they allowed clinicians to test patients, epidemiologists to survey populations, and officials to screen donated blood to protect the blood supply from HIV.

With both a clinical definition of AIDS and a screening test for HIV, officials could map the spread of the epidemic more accurately. Through the 1980s the United States had the greatest number of cases of AIDS, with 100 000 by 1989 and 200 000 by 1991. By the mid-1980s, however, concern had begun to shift to Africa. The first cases of AIDS in Africa had been described in Uganda in 1982. Reports from Zaire, Zambia, and Rwanda of patients with slim disease, KS, thrush (oral candidiasis), and meningitis emerged in 1983 and 1984. By 1985, with additional cases in Kenya and Tanzania, the WHO began to fear a vast epidemic in Africa. These fears have been realized: fully two-thirds of all cases of HIV have been in sub-Saharan Africa. The first cases

of AIDS in Asia were reported in Thailand in 1984. Reported cases of AIDS, however, remained rare for several years. Rapid spread began in 1988 with prevalence among IDUs and commercial sex workers quickly approaching 50%. By 1991 HIV had spread into the general Thai population, with 10–15% of military conscripts testing positive for the virus. In contrast to the rapid spread in these areas, many regions were largely spared during the 1980s. There were few cases of AIDS in Japan in the 1980s and those were largely limited to transmission from blood products, which were often imported from the United States. The Soviet Union and eastern European countries reported few cases before the breakup of the Soviet empire, and most of the acknowledged cases came from iatrogenic transmission. For instance, in 1990, Romania reported HIV among 2000 children who had been abandoned by their parents. According to folk practice, many newborns received small blood transfusions to increase their strength; this practice exposed the infants to unsterilized needles and a contaminated blood supply. However, even countries that were spared during the 1980s experienced accelerating epidemics in the 1990s. China, for instance, reported very few cases in the 1980s, mostly among foreigners or people who had traveled abroad. However, in the mid-1990s, the virus began to spread among IDUs and commercial blood donors. India similarly saw few cases in the 1980s, but by the mid-1990s, HIV was spreading through drug use, the blood supply, and heterosexual contact.

AIDS Before Effective Treatment: Fear and Blame

As scientists struggled to characterize AIDS and HIV, the epidemic caused considerable suffering and generated a worldwide health crisis. The epidemic began at a moment of relative complacency, especially in the developed world, concerning epidemic infectious disease. Not since the influenza epidemic of 1918–20 had an epidemic with such devastating potential struck. Developed countries had experienced a health transition from the predominance of infectious to chronic disease and had come to focus their resources and attention on systemic, noninfectious diseases. In this respect, AIDS appeared at a historical moment in which there was little social or political experience in confronting a public health crisis of its dimension. The epidemic fractured a widely held belief in medical security.

Not surprisingly, early sociopolitical responses were characterized by blame and discrimination. AIDS first appeared among homosexuals and IDUs, some of the most marginalized groups in society. Echoing earlier assessments of other sexually transmitted diseases (STDs), observers divided victims of HIV into categories: the ‘innocent victims’, who acquired their infections through transfusions or perinatal exposure, and the ‘guilty perpetrators’, who engaged in high-risk, morally condemnable behaviors. Since the disease was associated with ‘voluntary’ behaviors considered to be immoral, illegal, or both, individuals were typically blamed for their disease (Figure 1). Some religious groups in the United States, for example, saw the epidemic as an occasion to reiterate particular moral views about sexual behavior, drug use, sin, and disease. AIDS was viewed as ‘proof’ of a certain moral order. Hostile commentators called for a series of regressive, even punitive, measures to control the epidemic, including universal testing and quarantine. While such measures were never implemented in the United States, victims did suffer from discriminatory behavior, including loss of jobs, housing, and insurance. Homophobia became more visible as violence against gays and lesbians increased. The Food and Drug Administration (FDA) barred blood donations by members of the risk groups, including all Haitians. As the global extent of HIV became clear in the mid-1980s, the nature of blaming and bias also globalized. Early commentators condemned African behaviors that had supposedly spread the disease from monkeys to humans, such as the reported use of monkey blood as an aphrodisiac. Others blamed ecological disruption, particularly the destruction of tropical rain forests. In 1985 Soviet and Indian media reported that HIV had been created by biological warfare experts in the United States and released in Zaire in 1978. This theory received extensive international attention until it became clear that it had its origins in rumors actively spread by the KGB starting in 1983.

This early period of the epidemic in the United States also saw considerable fear of casual transmission despite reassurances that HIV could only spread through blood or sexual contact. A 1985 poll showed that 47% of Americans felt that infection could be transmitted through shared drinking glasses and 28% feared infection through toilet seats. The link between AIDS and receiving blood transfusions became transformed into belief that one could be infected by donating blood. Realtors in California were instructed to warn customers if a house had previously been owned by someone with AIDS. In some communities, parents

Figure 1 In the early years of the acquired immune deficiency syndrome (AIDS) epidemic in the United States, AIDS was associated with a series of stigmatized behaviors, as in this poster indicating the risk of shared needles among intravenous drug users. Such stigmatization blamed victims for their disease and hindered early public health efforts to contain the spread of HIV.

protested when HIV-infected school children were permitted to attend school. In one instance, a family with an HIV infected child – an ‘innocent victim’ – was driven from a Florida town when their home was burned down. As the disease, deadly and poorly understood, continued to spread, governments and victims’ advocacy groups struggled to make difficult decisions. The debates about bath houses are particularly revealing. In the 1970s an outbreak of hepatitis B revealed that these bath houses, and the sexual behaviors they facilitated, had become dangerous sites of disease transmission. In the early 1980s they were recognized as a dominant site of transmission of HIV. Many public health officials demanded that they be closed. The gay community was torn between those who saw bath houses as an essential expression of gay identity and those who feared the growing impact of AIDS. San Francisco shut down its bath houses in 1984 but similar efforts failed in Los Angeles.

The United States government initially showed little interest in AIDS. The defined risk groups had little political clout, and even less political appeal to the conservative administration of President Ronald Reagan. Failing to display leadership crucially needed in the early years of the epidemic, his administration repeatedly denied the need to make special appropriations for HIV and AIDS. However, as the potential ramifications of the epidemic became evident, national institutions began to mobilize. Congressional appropriations for research and education rose steeply. The National Academy of Sciences and a Presidential Commission both issued prominent reports. Meanwhile, international programs proliferated. Medical researchers organized a series of International AIDS Conferences, beginning in 1985. The World Health Organization established a Global Program on AIDS in 1986 to coordinate international efforts at epidemiologic surveillance, education, prevention, and research. The WHO also tried to guide responses to the epidemic, lobbying against the use of coercive measures, such as Cuba’s experiment with mandatory isolation of HIV-infected individuals. Instead, it advocated for the use of less restrictive measures to contain the epidemic.

Circumstances changed dramatically in 1985 with the development and wide implementation of screening tests. Just as the CDC definition of four risk groups shaped the early years of the epidemic, the ELISA and Western Blot generated a new range of responses to the epidemic. The tests quickly became a crucial method of reassurance. For the first time, people could know whether or not they were infected, without the uncertainty of the long latency that preceded the symptoms of AIDS. The tests also allowed public health officials to reestablish the safety of the blood supply. Prior to this, blood banks could only reduce risk by restricting donations from defined risk groups and testing for various surrogates, such as hepatitis B, a virus that shared many of the epidemiological characteristics of HIV. But despite these methods, over 10 000 people were infected by blood products in the United States by 1985. However, with the implementation of universal screening, the safety of the blood supply quickly improved. Since then, there have been very few transfusion-related cases of AIDS in the United States.

The advent of screening, however, raised difficult issues about the balance of individual rights and public health. The ability to screen for HIV made it likely that people who were infected, but still healthy, would suffer the full burden of discrimination faced by people with AIDS. Many questions were debated. Should public health officials require mandatory reporting and case tracing of HIV? Should states demand premarital testing, as they did for syphilis? Should employers be able to screen prospective employees? Should health insurers be able to screen prospective customers? Should hospitals be able to test all patients, and should patients be able to demand testing of their doctors? The Department of Defense, citing the risks posed by its vaccination programs and by potential battlefield transfusions, began screening all recruits in 1985. Critics of this policy saw it as a thinly veiled effort to enforce the military’s ban on homosexuals. Heated controversy also arose in 1987 when Congress forced the CDC to add HIV to the list of ‘dangerous contagious diseases’ which would be used to ban immigrants from the United States, despite evidence that HIV was not easily communicable.

For the most part, the rights of privacy won out in the United States. Few states required reporting of HIV at a time when reporting of other diseases, from tuberculosis to syphilis, was routine. In other countries the situation was quite different. The Soviet Union, for instance, implemented a massive compulsory testing program. Travelers, homosexuals, soldiers, pregnant women, prisoners, and those thought to engage in casual sex were all tested, 142 000 000 altogether. Infected foreigners were banned from entering the country. The advent of screening also set the stage for a series of tragic scandals. In the United States, public and private blood banks implemented screening relatively quickly. In other countries, notably France and Japan, the tests were not immediately implemented. Thousands of patients, particularly hemophiliacs, were infected. Subsequent investigations have ended in both civil and criminal convictions, with prison sentences for negligent officials and substantial payments to infected victims.

Although the ability to screen for HIV reduced many of the fears associated with the epidemic, many new fears quickly emerged. By 1986, two factors fueled increasing fear in developed countries that heterosexual spread would bring HIV into the general population. First, public health officials began to shift emphasis from the stigmatized ‘risk groups’ to more precise ‘risk behaviors’, stressing that dangerous behaviors such as needle sharing and anal intercourse could be found among people not identified as IDUs or homosexuals (Figure 2). Second, epidemiologists realized that heterosexual transmission was the dominant mode of spread in Africa and Haiti. Since these epidemics were believed to have begun earlier than in Europe and the United States, they were perceived as glimpses into the future of AIDS in Europe and the United States.

The fears were exacerbated by slow progress in developing treatments for HIV and AIDS. Many treatments were hailed initially, including interleukin-2, alpha interferon, bone marrow transplants, heteropolyanion-23 (HPA-23), and various immune stimulants. However, subsequent work inevitably showed them to be both toxic and of little value. Vaccines proved similarly elusive. When Gallo announced the discovery of his virus in 1984, federal officials optimistically predicted that a vaccine would be available within 2 years. By the end of the decade, however, researchers had little to show for their efforts other than skepticism and pessimism. In the absence of treatment, physicians and patients had little to offer people with HIV. Patients tried diets and alternative medicines to delay the progression to AIDS. Doctors could only work to prevent, and then treat, the devastating opportunistic infections.

Figure 2 During the late 1980s, public health officials increasingly recognized the threat of spread of HIV through heterosexual contact. Campaigns such as this one, moving outside of the traditional risk groups, encouraged women to protect themselves from incurable infection with HIV.

Although there was little that could initially be done to help people infected with HIV, public health officials knew everything that they needed to know to prevent the spread of the epidemic. Once the two primary modes of transmission had been identified – sexual intercourse and needlesharing by IDUs – two modes of prevention became obvious: widespread distribution of condoms and sterile needles. These techniques, combined with screening programs, could have slowed the epidemic. Some countries, notably the Netherlands, England, and Canada, did implement such programs. However, it quickly became clear that a diverse range of obstacles prevented effective deployment of public health programs. In the United States, for instance, the conservative federal government criticized condom and needle distribution programs as condoning morally and legally sanctioned behaviors. In 1988 Congress criminalized needle distribution programs. In the absence of federal support, grassroots needle exchange programs were begun in Boston, New Haven, New York, and San Francisco. Some programs received support from local governments, while others faced opposition and arrests. Such marginalization seriously impaired efforts to slow the spread of HIV.

By the end of the decade, the panic created by the emergence of AIDS had settled into a new equilibrium. Incidence rates began to level off in Europe and the United States. Public faith in the safety of the blood supply had been restored. Education efforts curtailed the spread of HIV among homosexuals. Fears that HIV would spread into the general population diminished. New cases remained confined to marginalized groups, notably urban minority populations. AIDS was no longer seen as a wildfire epidemic that would sweep the globe and threaten civilization. Once compared to the great epidemics of the past – plague, cholera, and influenza – AIDS now evoked comparisons to chronic diseases, particularly cancer. It had become routinized. Some observers feared that this new complacency would have adverse consequences. Public health officials in the United States, for instance, feared that increased public apathy would lead to decreased vigilance and allow a resurgence of the epidemic (Figure 3). Meanwhile, the view in developing countries was much bleaker. HIV continued to spread quickly in sub-Saharan Africa. Health officials faced difficult choices. Should they recommend that HIV+ mothers breast feed their children, which risked transmitting HIV, or should they encourage use of infant formulas, which exposed the children to contaminated water supplies? Seeing no good solution, the WHO supported breast feeding in the late 1990s. HIV also began to spread in countries, such as Thailand and India, and then China, that had initially been spared. Despite this, developed countries, no longer fearing a global pandemic, had become less supportive: international assistance for AIDS actually dropped between 1991 and 1992. Although some progress had been made, the epidemic continued.

The Development of Effective Treatments

As soon as HIV was identified, pharmaceutical companies began screening drug compounds for antiviral activity. In 1985 researchers realized that azidothymidine (AZT), which had been developed as an anticancer drug in 1964, blocked reverse transcriptase, an enzyme essential to the viral life cycle. On the basis of promising results from clinical trials, Burroughs Wellcome received authorization to market AZT in 1987. However, initial enthusiasm that AZT might be a magic bullet for HIV quickly gave way to frustration. The drug had many toxic side effects. Long-term studies showed that AZT conferred no survival benefit, in part because patients quickly developed resistance to the drug. Meanwhile, the research process became highly politicized. AIDS activists protested cumbersome FDA regulations that slowed the approval of new drugs. AIDS Coalition to Unleash Power (ACT UP), founded in 1987 by playwright Larry Kramer, issued scathing critiques, sought increased funding for drug research, and demanded more rapid access to promising treatments. In October 1988, ACT UP took over the FDA offices in Washington, DC, to bring attention to the plight of patients who died while the FDA worked to decide whether or not to approve new drugs. ACT UP also

Figure 3 Belief that HIV would not spread widely beyond traditional risk groups, or beyond marginalized urban populations, generated considerable apathy among many people. Public health officials tried to overcome this apathy by highlighting the general threat that would be posed if HIV was not acknowledged and managed.

organized drug sharing, buyers clubs, and basement laboratories to provide underground access to potentially valuable treatments. Such advocacy eventually led to major reforms in FDA policy, facilitating the testing and licensing of new treatments for HIV and AIDS. Another problem with AZT quickly rose to the forefront. When the drug was approved by the FDA in 1987, it costed roughly \$10 000 per patient per year of treatment. While this might have been within reach of people with HIV in Europe and the United States, international health activists realized that few developing countries had the resources to provide such an expensive treatment. At the Fourth International AIDS Conference in Stockholm in 1988, officials debated ways of getting treatment to the poor worldwide.

Realizing that AZT would not solve the challenges posed by HIV, researchers and drug companies continued to seek new and better treatments. By 1991 several new reverse transcriptase inhibitors became available (ddI, ddC, Lamivudine (3TC)). Clinicians hoped that combination therapy would be more powerful than AZT alone. While this proved to be true, even a combination of these drugs did not stop the infection. Resistance continued to emerge quickly. Moreover, clinical experience showed that even when patients had an excellent clinical response to therapy, the virus could survive, dormant, in various parts of the body (e.g., the testes). There seemed to be no way to completely eradicate the infection and cure patients. New hope came in 1994 when a major research trial (ACTG 076) showed that AZT could reduce the risk of transmission of HIV from pregnant women to their children by over 60%, from 20 to 8%. This gave patients greater hope that they would not transmit the infection to their children, and it provided a method for preventing a significant burden of new cases of HIV. Efforts to implement campaigns against maternal-to-child transmission, however, also became mired in controversy. The 6-month course of AZT used in the research study cost \$800 per patient, a sum beyond the reach of most patients in developing countries. Researchers wanted to know whether or not a shorter course, that cost only \$50, would be as effective. The quickest way to learn this would be to compare a short course of AZT to a placebo control group. A 1997 trial of a such shorter, cheaper regimen became embroiled in fierce controversy over what ethical guidelines should regulate international health research. Angry confrontations among researchers united by their desire to reduce the suffering created by HIV demonstrated the complicated scientific, social, and moral problems raised by the epidemic.

While health officials attempted to optimize the implementation of reverse transcriptase inhibitors, researchers continued to study the biology of HIV intensively. By 1991 they hoped that they would soon be able to block the HIV protease, crippling the activity of HIV. The first such protease inhibitor, Saquinavir, was approved by the FDA in December 1995. To maximize its efficacy and to minimize the emergence of resistance, clinicians combined the protease inhibitor with two reverse transcriptase inhibitors. The flexibility of such regimens increased in 1996 when researchers developed a third class of drugs, the non-nucleotide reverse

transcriptase inhibitors (e.g., nevirapine). Combination 'triple therapy' (initially called HAART, for highly active antiretroviral therapy, but now generally referred to as ART) proved to be a powerful weapon against HIV. Patients who had been near death from AIDS were miraculously revived: not cured, but restored to health, an effect that quickly became known as the Lazarus syndrome. AIDS mortality dropped quickly in western Europe, the United States, Canada, Australia, and New Zealand (Figure 4). AIDS, which had been the leading cause of death in young men in the United States in 1995, fell to fifth place. The incidence of HIV began to decrease as well. Physicians hoped that protease inhibitors might succeed where earlier drugs had failed and actually eliminate HIV from patients, curing them of their disease. At the 11th International AIDS Conference in Vancouver in 1996, protease inhibitors were celebrated as a 'quantum leap' in the treatment of HIV. Another major advance also appeared in 1996: viral load testing. The initial blood tests for HIV relied on detection of antibodies produced by the body in response to infection. While both sensitive and specific, these tests often did not become positive until several months after infection. The viral load test, in contrast, used polymerase chain reaction (PCR) technology to detect directly viral RNA in the patient's blood. This had two advantages. First, it could detect the virus much earlier in the infection. Second, it could be quantified to measure the activity of the infection. Changes in viral load could then be used to gauge prognosis and response to treatment.

Motivated by the optimism that followed the development of protease inhibitors, the United Nations created a new program devoted to AIDS. However, as had happened with the advent of AZT, a series of obstacles quickly emerged that threatened to undermine the efficacy of combination ART. First, the initial ART regimens were complex, requiring up to 16 pills taken at various times during the day. Outcomes in clinical practice were inferior to those attained in clinical trials, presumably because patients struggled to adhere to the complex regimens. Physicians feared that imperfect adherence to drug regimens would facilitate the emergence of resistant strains. Second, it became clear that the virus could become resistant to each class of medications, even when they were used carefully in combination. Third, patients developed a series of side effects in response to protease inhibitors, particularly lipodystrophy, a disruption of fat metabolism that could increase the risk of diabetes and heart disease. Fourth, researchers increasingly realized that the ability of HIV to insert its genetic material into the genome of host cells made eradication of HIV from an individual nearly impossible. Reservoirs of infected cells persisted, even when viral load became undetectable in patients' blood. If treatment was ever stopped, these internal reservoirs of HIV could become seeds of reinfection. Finally, the regimens were extremely expensive, initially costing \$10 000–\$20 000 per patient per year, a cost beyond the means of the developing countries where most infections occurred. By the late 1990s a familiar pattern had been established. Public health officials knew that powerful methods could prevent the spread of HIV, but these were rarely utilized to their full potential. Physicians had developed promising new treatments, from AZT to ART, but these faced difficult obstacles, including drug resistance, side effects, and cost. While better treatments could always be developed, the greatest challenge became making good use of existing technology.

Figure 4 Rate of death from human immunodeficiency virus (HIV). Death rates from HIV in the United States climbed steadily through the 1980s and early 1990s, peaking in 1995. The introduction of protease inhibitors and combined anti-retroviral treatment led to a dramatic reduction in HIV death rates. Bringing this treatment to all populations in the United States, and worldwide, has proven exceedingly difficult. Reproduced from CDC, Divisions of HIV/AIDS Prevention, Slide Series L285, Slide #4.

The Challenge of Providing Care

Throughout the history of AIDS, the nature of the epidemic had depended on where it took place. Modes of transmission varied significantly from country to country, as did the most prevalent opportunistic infections. These geographic variations persisted over the first three decades of AIDS. By 2000, however, a new disparity had emerged, one in many ways more troubling. For the first time a technology existed that could control, though not cure HIV. Patients in developing countries had good prospects for accessing ART and experiencing substantial gains in life expectancy after infection. Meanwhile, ART initially remained out of reach in developing countries, creating enormous disparities in the experience of infection.

The advent of ART led to substantial changes in the nature of the AIDS epidemic in developed countries. Since 1981, the United States had seen over one million cases of AIDS with over 500 000 deaths, the eighth highest total for a country worldwide. Mortality rates had climbed steeply from the 1980s to the 1990s, reaching over 16/100 000 in 1995. With ART, however, the United States witnessed an 80% reduction in mortality, with the rate falling to under 6/100 000. With mortality declining, a diagnosis of HIV no longer seemed to be the life-ending event it had been in the 1980s. Testing became much more widespread. In 1996 the FDA licensed home test kits for HIV. Although testing services were regulated to ensure that patients who received positive test results by telephone also received adequate counseling, HIV testing became nearly as simple as home pregnancy tests. Testing technology continued to improve, allowing clinics to provide results within 30 min. Treatment, even though expensive, was well funded by both insurers and government programs. As a result, everyone with HIV in the United States had access, in theory, to ART. Pharmaceutical companies also produced complex pill formulations, allowing a one-pill-a-day regimen for people infected with nonresistant strains. Widespread access to treatment led to a dramatic increase in life expectancy for people with AIDS: over 13 years by 2006, a number expected to grow with continuing use of the powerful medications.

Decreased mortality, easier testing, and better access to treatment all contributed to the routinization of HIV in the United States. Health officials, physicians, and patients became more willing to accept control measures that, during the height of AIDS fear, would have been dismissed as unacceptable infringements of civil liberties. By 1998, 30 states (but representing only 30% of all cases) had established some form of mandatory reporting. The CDC worked hard to increase the coverage of its HIV surveillance efforts. In 1999 and again in 2005, the CDC pushed all states to report all cases of HIV to the CDC. The CDC argued that this was already done routinely for many communicable diseases and that there was no longer any reason to treat HIV differently. Eventually, tying mandatory reporting to over \$1 400 000 000 in federal aid, the CDC achieved this goal: by the end of 2007, the United States finally had a system of nationwide mandatory reporting in place, something that had taken 30 years to implement. Working in parallel, physicians pushed to make HIV testing a routine part of annual physical exams and prenatal care. Officials heralded the end of 'AIDS exceptionalism': while special measures to protect privacy had been appropriate during the early years of AIDS, such protections were increasingly seen as missed opportunities for controlling the epidemic.

However, some old problems persisted. Strong moral judgments about patients and modes of infection continued to disrupt efforts to prevent and contain HIV. Condom and clean needle distribution programs remained mired in political debate. In 1998 President William Clinton refused to lift the ban on federal funding for needle exchange programs. Political opposition to needle exchange programs continued under President George W. Bush, despite evidence that they were the most effective means of preventing HIV among IDUs, and that they might actually decrease the prevalence of drug use, presumably because the site of needle exchange programs became a valuable site for educational programs. Public health officials also feared that declining mortality and routinization would lead to complacency and carelessness about prevention. Although mortality dropped, the incidence of HIV remained stable, at roughly 40 000 new cases each year since 1992. Most men (58%) continued to be infected through homosexual contact; incidence even began to increase among young homosexual men. Among women, however, most cases (71%) came through heterosexual transmission.

Even more worrisome was the accelerating spread of HIV among the most marginalized communities in the United States. By the mid-2000s, African Americans made up 50% of all cases, even though they represented only 12% of the population. The incidence among African Americans compared to whites was 7 times higher for men, and 21 times higher for women. Women also made up an increasing share of the cases, especially among younger age groups. Among HIV+ teens, for instance, nearly two-thirds were women, mostly African Americans, infected through heterosexual contact. Enormous disparities existed not just for incidence of HIV, but also for outcomes after infection. Treatment failure was especially prevalent in minority populations, with 50% of AIDS deaths occurring in these populations. The AIDS mortality rate in Boston and New York City, for instance, was roughly 15 times higher in black women than in white women. Many obstacles prevented successful implementation of ART in these populations. One study found that only 37% of patients in Baltimore had undetectable viral loads after 1 year of treatment. Such data suggested that in the United States, where adequate resources existed to control HIV and AIDS, failures of social and political will disrupted responses to the epidemic.

The situation outside of the United States was even more complex. Some developing countries, notably Brazil, successfully implemented ART to reduce mortality from AIDS substantially. Many more countries, however, were devastated by HIV, a testimony to the global failure to contain the epidemic. By the end of 2006, an estimated 33 200 000 people lived with HIV, nearly 0.8% of the world's population. Despite the ability, in theory, to prevent infection through abstinence, condom use, and clean needle distribution, over 2 500 000 people were newly infected in 2006. Despite the ability of ART to extend life expectancy dramatically, nearly 2 100 000 died of HIV in 2006. Much of the burden of the epidemic remained in sub-Saharan Africa. Over 60% of people living with HIV, and over 70% of deaths from AIDS, were in sub-Saharan Africa, where overall prevalence of HIV among adults reached 5.9%. Many countries in southern Africa had adult prevalence rates over 20%. Swaziland, suffering the most intense

epidemic in 2006, had an estimated prevalence rate of 33.4%. South Africa continued to have the highest number of cases, 5 500 000, without evidence that spread of infection had slowed. Most of the people living with HIV continued to be unaware of their infection.

In contrast to southern Africa, many other regions of Africa experienced much less severe epidemics. In eastern and western Africa, many countries had prevalence rates below 5%, and some remained below 1%. Outside of Africa, rates also remained low, but with concerning evidence of rapid increases in the late 1990s and early 2000s. Rates of HIV increased by 70% in eastern Europe and central Asia between 2004 and 2006, with 90% of this increase confined to Ukraine and Russia, where most spread occurs among IDUs. Rates have also increased in East Asia, south Asia, the Middle East, and north Africa. Although China reported only 650 000 cases overall, nearly half among IDU, prevalence in that group rose in the early 2000s, reaching over 50% in some Chinese provinces. Increased rates have also been seen among pregnant women. India, poised to displace South Africa as the country with the highest number of cases, experienced a highly varied epidemic, with most cases confined to industrial centers in the south, west, and northeast. Preliminary data suggest that prevention programs had begun to slow transmission. A few countries, notably Cuba, have been largely spared from the epidemic, with prevalence less than 0.1%.

The HIV epidemic has had striking demographic impacts. AIDS has orphaned 15 000 000 children, of whom 80% live in sub-Saharan Africa. Many sub-Saharan Africans have also seen marked decreases in overall life expectancy. Although life expectancy had reached 65 years in Botswana by the late 1980s, it fell to less than 36 years because of HIV. Similar drops occurred in Zimbabwe and Swaziland. Throughout southern Africa, AIDS became a major barrier to economic development and political stability. Tragically, in the absence of development and stability, AIDS will remain difficult to control. How has this happened, 20 years after the development of successful preventive strategies and 10 years after the development of effective treatment?

When ART became available in the late 1990s, many leading health officials believed that it could not be implemented in developing countries. In 1998, for instance, many prominent officials argued that ART was inappropriate for poor countries. The treatment was too expensive, far exceeding the annual per capita health expenditures of every country. It was too difficult to implement, requiring sophisticated testing services and health infrastructure. If implemented imperfectly, it would facilitate the emergence of resistant strains, which would then threaten populations worldwide. Instead of treatment, health officials emphasized prevention. One influential comparison of treatment and prevention concluded that prevention was 28 times as cost effective as ART and argued that funding ART would, overall, lead to a greater loss of life. The focus on prevention achieved a powerful consensus. At the 13th International AIDS Conference, held in South Africa in 2000, over 5000 attendees signed the 'Durban Declaration': while ongoing research might lead to cheaper treatments, even a vaccine, AIDS campaigns needed to focus on prevention of sexual transmission.

Proponents of prevention had evidence that such approaches could be successful. Even amidst the many calamities of the HIV pandemic, some countries achieved remarkable success at slowing the spread of HIV through preventive programs including health education, drug treatment, employment, and distribution of condoms and clean needles. In Uganda, for instance, education programs emphasized abstinence and condom use among sexually active teens. Such programs decreased prevalence, which peaked in the late 1980s and fell through the 1990s. Knowing that the presence of other STDs substantially increased the risk of transmitting HIV, officials in Tanzania implemented an STD treatment program that led to a 42% reduction in the incidence of HIV. Prevalence rates have also declined in Zambia, Kenya, Ghana, Rwanda, and Burkina Faso. Countries in southern Africa generally had less success, with Zimbabwe standing out as an exception. Despite substantial poverty and civil unrest, the prevalence of HIV among pregnant women fell from over 30% in 2000 to 24% in 2004. There have been successes outside of Africa as well. Aided by WHO, the Thai government began a major campaign for public education and condom use by prostitutes. As a result, prevalence among commercial sex workers declined significantly over the 1990s. Overall incidence in Thailand has decreased from 143 000 in 1991 to only 18 000 in 2005.

Critics, however, argued that strict emphasis on prevention consigned the 30 000 000 people living with HIV to death. They insisted that large-scale treatment programs must be implemented, both because of belief in equity and social justice and because treatment could potentially be a highly effective form of prevention: if reducing viral loads to undetectable levels decreases the infectiousness of HIV+ individuals, then comprehensive treatment would substantially slow the spread of HIV. Arguing that no developed country would tolerate withholding treatment from a large sector of its own population, treatment activists called on developed countries to make resources available for global treatment programs. Noting that the roughly \$8 000 000 000 needed each year for global AIDS control represented only 0.044% of the GDP of the 22 wealthiest countries, they argued that resources for AIDS treatment clearly existed. The challenge was simply one of priorities. Treatment advocates were especially critical of the use of costeffectiveness analysis to support prevention at the expense of treatment, arguing it would be better to mobilize the resources needed for both. When Lee Jong-Wook took over as director general of the WHO in 2003, he pushed aggressively for treatment. With only 2% of HIV+ people having access to ART, he argued that a worldwide health emergency existed.

Although such advocacy of treatment was initially seen as naïve and unrealistic, remarkable progress was made quickly. Success came from several directions. First, a series of reforms substantially reduced the cost of HIV treatment. In the late 1990s, pharmaceutical companies in Thailand, Brazil, and India began producing generic versions of HIV medications, in violation of international patent law. Brazilian companies, for instance, reduced the cost of ART in 1996 from \$15 000 per person per year to only \$4000. In 1998 South Africa attempted to import generic ART from these companies. Fearing that this would serve as a precedent for violations of patent rights worldwide, 39 pharmaceutical companies sued South Africa, initially with the support of the United States government. This lawsuit proved to be immensely embarrassing for the United States, which was seen as protecting the interests of profitable corporations while millions of people died from AIDS. As a result, in 2000, President Clinton

issued an executive order forcing the companies not to enforce their patents in South Africa. Nearly simultaneously, those companies agreed to slash prices for their drugs in developing countries by over 90%. This created a two-tiered system in which developed countries paid full price while developing countries received steep discounts. Such arrangements were formalized in 2001 by the World Trade Organization's agreement on Trade-Related Aspects of Intellectual Property Rights. Known as the Doha Declaration, this agreement gave governments the right to take certain measures to protect public health. In the midst of a health crisis, governments may impose compulsory licensing and allow local companies to produce medications in violation of international patents. Seen as a recognition of the primacy of public health over private property, the Doha Declaration enabled further reductions in the cost of ART. The nongovernmental organization Médecins Sans Frontières worked with Cipla, an Indian pharmaceutical company, to produce combined ART at a price of only \$350 per person per year. Following this lead, the Clinton Foundation negotiated further price reductions in 2003, to only \$140 per person per year.

The marked reduction in the price of ART motivated the second major development, a dramatic increase in funding for global AIDS control. When ART became available, the United States provided limited funding for international AIDS programs, only \$121 000 000 in 1998. Activists asserted that much greater resources existed and that corporations had the knowledge needed to deploy treatment effectively worldwide. As prices for ART fell by 99% in the early 2000s, resistance to treatment programs dissipated and donor countries began to develop funding mechanisms. In 2002 the Global Fund to Fight AIDS, Tuberculosis and Malaria was created as a partnership between governments, communities, and industry to direct resources to areas suffering from those diseases. Although it received only a fraction of the funding it needed, the Global Fund made progress in many areas. In 2003 President Bush increased the commitment of the United States, promising \$15 000 000 000 in AIDS assistance over 5 years; in 2007 he called for another \$30 000 000 000 to extend this 5 years further. This initiative, which became the President's Emergency Plan for AIDS Relief (PEPFAR), significantly increased ART treatment worldwide (Figure 5). Private donors, notably Bill Gates and Warren Buffett, also made substantial contributions. All told, funding available for global AIDS treatment increased from only \$292 000 000 in 1996 to over \$8 000 000 000 in 2005.

Decreased cost of ART and increased funding for global AIDS made both prevention and treatment possible on a previously unprecedented scale. Actual implementation proved difficult. One crucial challenge was ensuring that treatment, once started, was never interrupted, something that would facilitate the emergence of resistant strains. This required careful attention to planning and logistics. Experience also showed that simply making treatment available, through voluntary counseling and testing, did not get enough patients into treatment. The most successful HIV control programs instead tied HIV services more broadly to the provision of primary health care services, especially STD prevention and treatment, as well as maternal and child health programs. Wraparound services, including nutrition assistance, substance use treatment, and social support, made it possible to achieve high rates of treatment compliance even in the world's poorest regions.

However, as happened in the United States, a variety of political factors conspired to undermine optimal implementation of HIV prevention and AIDS treatment. President Thabo Mbeki's opposition to ART delayed its widespread introduction into South Africa until 2004. Meanwhile, critics argue that domestic social politics in the United States interfered with AIDS programs funded by the United States. Specifically, the Bush administration mandated that one-third of the funding it gave to prevention programs be used for advocacy of abstinence and monogamy, efforts that were not always well suited to local regions. As has happened since the 1980s, ideology and pragmatism remained in tension, disrupting HIV prevention.

One of the most dramatic efforts to increase AIDS treatment worldwide came in 2003 when the WHO launched its 3 by 5 campaign, an effort to get 3 000 000 people in developing countries on ART by 2005. This program met fierce resistance from critics and skeptics. Some complained that the target of 3 000 000 represented only half of the people who needed treatment. Others

Figure 5 The PEPFAR testing center in Migori, Kenya. In the early to mid-2000s, a variety of programs made anti-retroviral therapy (ART) available to people in developing countries on an unprecedented scale. The most effective programs combined voluntary counseling and testing with access to ART and a broad range of primary care services. Reproduced from *The Power of Partnerships: Third Annual Report to Congress on PEPFAR* (2007), p. 103 (<http://www.pepfar.gov/press/c21604.htm>).

worried that infrastructure did not exist in enough countries and that the WHO did not control enough funding to make this possible. The outcome of 3 by 5 was a mixed success. By the end of 2005, only 1 300 000 people were on ART in developing countries. Few of the target countries had reached the goal of getting 50% of eligible patients on treatment. However, this still reflected a threefold increase over 2 years. Moreover, some countries, notably Botswana, made enormous progress, bringing ART to 85% of the people in need. Such successes demonstrated the feasibility of extensive treatment in developing countries and fueled growing enthusiasm for ART. Countries acting on their own, such as Brazil, or in collaboration with either PEPFAR or WHO brought ART to millions of patients. By the end of 2006, the Global Fund reported that it had 770 000 on ART, PEPFAR 822 000, and WHO 1 800 000. South Africa alone claimed over 1 000 000 people, a tenfold increase since 2003. Despite such progress, a majority of people who would benefit from ART – over 70% – still did not have access. World leaders repeatedly pledged to do better. In 2006, for instance, the General Assembly of the United Nations committed member nations to provide universal access to prevention and treatment by 2010. While most global health leaders supported this goal, no one produced a clear road map for how to make it possible amidst daunting obstacles.

Health officials believe that vaccines will ultimately provide the best solution for the long-term control and prevention of HIV in developing countries. An ideal vaccine would be safe, cheap, and stable enough for mass vaccination campaigns; it would provide long-lived protection; and it would be active against the diverse subtypes of HIV. Such a vaccine remains the Holy Grail of AIDS research. Despite more than 25 years of research, there has been little success. The first clinical trial of an AIDS vaccine began in 1998, but nothing promising enough for widespread use has been developed. Researchers predict that a vaccine will not be available for many years. Some even confess that the task might be impossible because of the ways in which HIV sabotages the immune system. But research continues with the hope that a partial success would still be valuable. Even a ‘therapeutic vaccine’, one that did not prevent infection but instead strengthened an individual’s response to infection, would help. Efforts to develop other measures to prevent infection have also been disappointing. Researchers have long tried to develop an anti-HIV microbicide that women would insert into their vaginas to protect themselves against infection by HIV+ partners. A series of clinical trials, however, have shown that each proposed microbicide actually increased rates of infection, presumably because of irritation of the vaginal mucosa.

New hope came from an unexpected direction. Epidemiologists had recognized by the 1990s that rates of HIV transmission were lower in countries where male circumcision was widely practiced than in countries where it was not. This led to the suggestion that circumcision somehow protected against HIV transmission. Several clinical trials were begun to test prospectively whether circumcision of adult men could be an effective means of reducing the spread of HIV. In 2006 researchers stopped two randomized trials prematurely because the outcomes were so dramatic: circumcision reduced transmission rates by over 50%. Since even a 50% reduction could have a substantial impact on the epidemic, circumcision could work as a powerful, if imperfect, vaccine. However, as with condoms and needle distribution, circumcision is tied to social beliefs and practices that might limit its popularity as a means of preventing HIV.

As AIDS approaches the end of its third decade, it has attained a complicated status, characterized by a series of striking disparities. Medical research and public health campaigns have produced some dramatic successes. Condom and clean needle distribution, as well as male circumcision, can substantially reduce the transmission of HIV. Such measures have been implemented in some countries. Furthermore, people who have become infected with HIV can control their illness with ART, increasing their life expectancy dramatically. However, a variety of social, economic, and political obstacles have disrupted successful implementation of these powerful technologies. Although AIDS mortality has decreased significantly in developed countries, marginalized minority populations experience marked disparities in both rates of infection and mortality. Although some developing countries have successfully deployed both prevention and treatment, AIDS continues to devastate sub-Saharan Africa, where the millions of people now infected with HIV will likely develop and die from AIDS. The impact on other areas, notably Russia, China, and India remains unclear. These countries have a limited window for containing the epidemic before beginning to suffer the decrease in overall life expectancy seen in southern Africa.

At every level, AIDS has been an epidemic created by, and starkly reflecting, inequalities within and between countries. Poverty creates dangerous vulnerabilities to HIV, and AIDS exacerbates poverty. The same inequalities that create the epidemic also hinder responses to it. While patients in wealthy countries have access to powerful treatments, the vast majority of victims do not yet. As a result, scientific success to date has served to expose economic inequality. In the mid-2000s, a strong consensus emerged that called for bringing access to effective prevention and treatment to all countries worldwide. Will it be possible to make universal access a reality? If such efforts contain the epidemic, will it be possible to maintain support for lifelong treatment for everyone now infected with HIV? Will a vaccine emerge that will someday replace ART as the cornerstone of global HIV campaigns? Unprecedented efforts will be needed, over decades, to implement the necessary medical, public health, and social reforms. Such efforts could have an enormous reward, preserving the health of populations worldwide and restoring health to the many areas already devastated by HIV and AIDS.

Glossary

Aspergilloma Pulmonary fungus ball consisting of a solid mass of hyphae growing in a lung cavity.

Aspergillosis Disease caused by the inhalation of some species of the genus *Aspergillus* resulting in growth of the fungus in the lungs.

Bioaerosol An airborne suspension of biological particles and microbial by-products.

Blastomycosis A symptomatic infection caused by the inhalation of the fungus *Blastomyces dermatitidis*.

Chickenpox Disease caused by the virus varicella-zoster.

Coccidioidomycosis Disease caused by the inhalation of *Coccidioides immitis* arthroconidia (also called San Joaquin Valley fever).

Cryptococcosis Disease caused by the fungus *Cryptococcus neoformans*.

Endotoxin A lipopolysaccharide component of the Gram-negative bacteria cell released during active cellular growth and after cell lysis that can cause respiratory distress when inhaled.

Enteric viruses Group of viruses related with the digestive system of hosts, including the genera Adenovirus, Calicivirus, Enterovirus, Rotavirus, etc.

Fomite An inanimate object that transmits infectious agents to a new host.

H5N1, H7N2, H9N2, and H7N3 Strains of avian influenza A viruses that have been linked to respiratory disease in humans.

Histoplasmosis Disease caused by the infectious fungus *Histoplasma capsulatum* that can manifest as mild flu-like symptoms to chronic lung disease that resembles tuberculosis.

HIV Human immunodeficiency virus

HPS Hantavirus pulmonary syndrome.

Legionnaires' disease A severe respiratory disease resulting from the inhalation of *Legionella pneumophila*.

Measles Term for the disease caused by the virus of the same name.

MERS Middle east respiratory syndrome

Mycobacterium tuberculosis The causative agent of human tuberculosis.

NLVs Norwalk-like viruses.

Pontiac fever A mild flu-like syndrome following inhalation of nonviable *L. pneumophila*.

Rubeola Another name for the disease measles.

SARS Severe acute respiratory syndrome.

SARS-CoV Severe acute respiratory syndrome associated coronavirus.

Sin nombre virus Causative agent of the majority of hantavirus pulmonary syndrome cases in the United States.

Defining Statement

Inhalation of airborne pathogenic microorganisms can elicit adverse human health effects including infection, allergic reaction, inflammation, and respiratory disease. This article discusses viruses, bacteria, endotoxin, and fungi that are dispersed through the air and can result in infection following inhalation.

Introduction

Inhalation exposes the upper and lower respiratory tracts of humans to a variety of airborne particles and vapors. Airborne transmission of pathogenic microorganisms to humans from the environment, animals, or other humans can result in disease. The lung is more susceptible to infection than the gastrointestinal tract as ingested microorganisms must pass through the acidic environment of the stomach before they can colonize tissue, while inhaled microorganisms are deposited directly on the moist

surfaces of the respiratory tract. Inhalation of microbial aerosols can elicit adverse human health effects including infection, allergic reaction, inflammation, and respiratory disease.

Bioaerosols

A bioaerosol is an airborne collection of biological material. Bioaerosols can be comprised of bacterial cells and cellular fragments, fungal spores and fungal hyphae, viruses, and by-products of microbial metabolism. Pollen grains and other biological material can also be airborne as a bioaerosol. Microbial aerosols are generated in outdoor and indoor environments as a result of a variety of natural and anthropogenic activities. Wind, rain and wave splash, spray irrigation, wastewater treatment activity, cooling towers and air handling water spray systems, and agricultural processes such as harvesting and tilling are examples of activities that generate bioaerosols outdoors. Indoors bioaerosols are generated and dispersed by mechanical and human activity. Industrial and manufacturing practices and biofermentation procedures can generate high concentrations of microbial aerosols. Heating, ventilation, and air conditioning (HVAC) systems, water spray devices (e.g., showerheads and humidifiers), and cleaning (e.g., dusting, sweeping, vacuuming, and mopping) result in the transport of microbial materials in the air. Talking and coughing generate bioaerosols from individuals, some of which may be infectious. Facilities with medical, dental, or animal care practices can generate infectious microbial aerosols.

The individual particle size of particulate material in bioaerosols is generally 0.3–100 μm in diameter; larger particles tend to settle rapidly and are not readily transported in the air. Virus particles are nanometer in size, bacterial cells are approximately 1 μm in diameter, and fungal spores are $>1 \mu\text{m}$. These microorganisms can be dispersed in the air as single units, but are often present as aggregate formations. The larger aggregates have different aerodynamic properties than single-cell units; therefore their dispersal may be different than single-unit particles. Aggregates of biological material also afford protection from environmental stresses such as desiccation, and exposure to ultraviolet radiation ozone and other pollutants in the atmosphere. Often bacterial cells and virus particles are associated with skin cells, dust, and other organic or inorganic material. During agricultural practices (e.g., during harvesting, and tilling), fungus spores are released from plant surfaces and the soil and raft on other particulate matter. This “rafting” affects the aerodynamic characteristics and the survival of the cells in the bioaerosol. When biological material is dispersed from water sources (e.g., splash, rainfall, or cooling towers and fountains), it is generally surrounded by a thin layer of water. This moisture layer also changes the aerodynamic properties and aids in the survivability of the microorganisms while airborne.

Airborne particulate will remain airborne until settling occurs or they are inhaled. Following inhalation, large airborne particles are lodged in the upper respiratory tract (i.e., nose and nasopharynx). Particles $<6 \mu\text{m}$ in diameter are transported to the lung where the 1–2 μm particles have the greatest retention in the alveoli. The average person inhales approximately 10 m^3 of air per day, which may result in an infective dose for some airborne pathogens. Diseases resulting from inhalation of bioaerosols include allergic reaction, irritation, inflammation, infection, and respiratory disease.

The by-products of microbial metabolism and foreign proteins of microorganisms and fragments of cells can result in allergic reactions and irritant responses. The inflammatory response and allergic reactivity can be debilitating to sensitized individuals in indoor and outdoor environments, and it has been demonstrated following exposure to airborne bacterial fragments present in airborne dust. However, the greatest adverse health impact following exposure to airborne microorganisms is associated with inhalation of infectious agents. These infectious agents include viruses, bacteria, and fungi. The following sections introduce representative pathogens of each grouping that are associated with the airborne route of exposure. [Table 1](#) provides a summary of the pathogens presented in this article.

Infectious Airborne Viruses

Viruses are noncellular units consisting of either DNA or RNA. They do not have self-directed biosynthesis and, therefore, require a living host cell for replication. Following inhalation, infectious viruses can establish in host cells of the respiratory tract. Some are translocated and infect the gastrointestinal tract and other tissues.

Influenza

Influenza is a contagious respiratory illness caused by flu viruses A, B, and C. There are subtypes of influenza type A viruses based on two proteins on the surface proteins of the virus, hemagglutinin (H) and neuraminidase (N). Many animals carry influenza A viruses, while influenza B viruses circulate among humans. Both influenza types A and B viruses cause epidemics of disease almost every winter. Influenza type C infections cause a mild respiratory illness and are not thought to cause epidemics. While symptoms can be mild, influenza may result in severe illness and death. The Centers for Disease Control and Prevention reports that there are more than 200,000 hospital admissions and 36,000 deaths per year in the United States due to influenza. All ages can have serious illness from influenza, but those more likely to have complications are people aged 65 years and older, people with chronic medical conditions, and very young children. Transmission of influenza viruses is from person to person in respiratory droplets expelled during coughing and sneezing. The droplets are propelled usually less than 3 feet through the air and deposited on people in close proximity. The presence of the virus has been confirmed in aerosol particles within the breathable fraction in a study performed in a hospital emergency room ([Blachere et al., 2009](#)). Fomites contaminated with settled infectious droplets can also serve as a vehicle for transmission of influenza.

Table 1 Characteristics of selected infectious microorganisms transmitted via the airborne route of exposure

Organism	Characteristics	Disease	Reservoir
<i>Aspergillus</i> spp.	Fungus, a mold with spherical spores ~1 µm in diameter, variety of species including <i>Aspergillus fumigatus</i> , <i>Aspergillus flavus</i> , <i>Aspergillus nidulans</i> , <i>Aspergillus terreus</i> , and <i>Aspergillus niger</i>	Aspergillosis, aspergilloma (fungus ball), allergic sinusitis, and allergic bronchopulmonary disease	Environment, compost and plant material, soil, dust, building materials
<i>Blastomyces dermatitidis</i>	Fungus; 8–15 µm spherical yeast cells	Flu-like illness, chronic lung disease	Moist soil enriched with decomposing organic debris
<i>Coccidioides immitis</i>	Fungus; 5 µm alternating barrel-shaped arthrospores	Coccidioidomycosis/ San Joaquin Valley fever	Desert soils with intermittent wet and hot dry cycles
<i>Cryptococcus neoformans</i>	Fungus; vegetative form (yeast cell) 2.5–10 µm, basidiospores 1.8–3 µm	Cryptococcosis	Pigeon droppings debris and soil associated with birds
Enteric viruses	Virus; RNA/DNA, ~20–100 nm	Gastrointestinal symptoms, meningitis, encephalitis, respiratory infections	Infected persons, surfaces
<i>Histoplasma capsulatum</i>	Fungus; dimorphic 2–5 µm oval cells	Flu-like symptoms, chronic lung disease, dissemination to other organ systems	Environment
Influenza viruses	Virus; single-stranded RNA, three distinct types (i.e., A, B, and C), 80–120 nm	Influenza, pneumonia, acute respiratory distress	Human respiratory secretions; avian flu associated with birds
<i>Legionella pneumophila</i> and <i>Legionella</i> spp.	Bacterium; vegetative Gram-negative bacillus, 0.5–1 µm by 2 µm	Legionnaires' disease and Pontiac fever	Ubiquitous in fresh and waste water environments, an intercellular parasite of protozoa
Measles virus (MeV)	Virus, enveloped, negative – sense, single-stranded RNA hantavirus, 100–250 nm	Rubeola: acute, febrile disease with an exanthematous rash, dry cough, sore throat, headache	Human – only known reservoir
Middle East respiratory syndrome – associated coronavirus (MERS-CoV)	Virus, enveloped, positive-sense single-stranded RNA	Acute respiratory distress syndrome, multi-organ failure, septic shock, death	Infected persons, bats and camels reservoirs
<i>Mycobacterium tuberculosis</i>	Bacterium; acid-fast, 0.2–0.6 µm by 1–10 µm	Tuberculosis	Infected persons
Severe acute respiratory syndrome – associated coronavirus (SARS-CoV)	Virus; RNA with helical symmetry, positive-sense single-stranded RNA	Acute respiratory distress	Infected persons
Sin nombre virus (SNV)	Virus; negative – sense, single-stranded RNA hantavirus	Hantavirus pulmonary syndrome (HPS)	Rodent urine, saliva, and feces especially <i>Peromyscus maniculatus</i> (deer mouse)
Varicella-zoster virus (VZV)	Virus; double-stranded DNA, 150–200 nm	Chickenpox	Humans – only known reservoir; virus may be dormant until reactivates as shingles

Avian influenza A viruses usually do not infect humans. However, cases of human infection with avian influenza viruses have been reported since 1997. Illness caused by several strains of avian influenza A viruses (e.g., H5N1, H7N2, H9N2, and H7N3) have been reported since 2004. The majority of human avian influenza infections have resulted from inhalation during direct contact with infected poultry or contaminated surfaces such as avian cages, or from the ingestion of uncooked blood of infected birds. Therefore, this influenza has been popularized as “bird flu.” The illnesses resulting from avian influenza infection in humans range from typical mild influenza-like symptoms (e.g., fever, sore throat, cough, and muscle aches) and conjunctivitis to more serious cases of pneumonia, acute respiratory distress, and other severe and life-threatening complications. To date, there have been no sustained human-to-human transmission of avian influenza A viruses, but because of the potential for these viruses to gain the ability to spread easily between people, monitoring for human infection and person-to-person transmission is important. In addition, recent studies have addressed the possibility of long-range transport of both, Influenza and Avian influenza viruses, using dust storms as a vehicle to be dispersed at farther distances (Chen et al., 2009, 2010).

Severe Acute Respiratory Syndrome

Severe acute respiratory syndrome (SARS) is a newly reported respiratory illness. It was first reported in February 2003 in Asia. Since then, it has also been reported in North America and Europe. It is a viral respiratory illness caused by a coronavirus, termed SARS-associated coronavirus (SARS-CoV). Exposure to SARS-CoV results from close personal contact with infected individuals. Transmission is generally the result of touching the skin of an infected person or objects contaminated with infectious droplets and then

transferring the virus to the new host's eyes, nose, or mouth. Coughing or sneezing by an infected individual also releases droplets into the air that are propelled a short distance (<1 m) and deposited on the mucous membranes of the mouth, nose, or eyes of persons who are nearby. It is possible that SARS can be spread further through the air by very small particles, and although it may be unusual, it has been confirmed in different environments (housing complex, aircraft, hospital facilities) (Wong et al., 2004; Olsen et al., 2003; Yu et al., 2004). Hand hygiene, use of gown, gloves, and eye protection when in contact with an infected individual, and use of an appropriate respirator minimizes the spread of SARS.

Middle East Respiratory Syndrome

Middle East respiratory syndrome coronavirus (MERS-CoV) emerged in 2012 in Saudi Arabia. Since then, a major outbreak occurred in 2015 in the Republic of Korea, and many other countries have reported positive cases (WHO, 2015). Human-to-human contact seem to be the principal way of transmission, however, its survival in aerosols has been positively tested, pointing to the airborne route as an alternative form of dispersal (van Doremalen et al., 2013). Genetic analyses of patients' specimens showed similarities between MERS-CoV and other coronavirus isolated from hedgehogs, bats and camels, suggesting their possible role as reservoirs (WHO MERS-CoV Research Group, 2013). Despite all these data, the exact way of transmission remains on debate. Pathology may vary from asymptomatic to have a fatal outcome. It starts with mild symptoms (fever, cough, etc.) followed by pneumonia with acute respiratory distress and multi-organ failure that may lead to death in 60% of the cases (WHO MERS-CoV Research Group, 2013; de Groot et al., 2013).

Enteric Viruses

Enteric viruses primarily cause gastrointestinal infections, but may also be responsible for more serious diseases such as respiratory infections, meningitis or encephalitis (Fong and Lipp, 2005). Adenovirus, enterovirus, norovirus, hepatovirus and rotavirus are some of the genera considered within this group (Bosch, 1998). They are typically transmitted by fecal contaminated water or food, but airborne dispersion has been considered in some major outbreaks (Kuo et al., 2009; Marks et al., 2000, 2003; Xu et al., 2013; Dick et al., 1987; Ho et al., 1999; Lin et al., 2002). In the case of norovirus, which causes diarrhea and sudden projectile vomiting, it has been estimated that over 30 million virus particles can be liberated during vomiting. Since the infectious dose is very low, 10^1 – 10^2 particles, airborne transmission within close contact is highly likely (Caul, 1994; Baert et al., 2008).

Hantaviruses

Hantavirus pulmonary syndrome (HPS) is a life-threatening disease caused by rodent-borne hantaviruses. It is characterized by severe pulmonary illness and a mortality rate of 30–40%. The sin nombre virus (SNV) causes the majority of HPS cases in the United States, and *Peromyscus maniculatus* (the deer mouse) is its predominant reservoir. The virus found in the rodent urine, saliva, and feces becomes aerosolized as mist from urine and saliva or dust from feces. Inhalation is the most common route of infection. However, touching the mouth or nose after handling contaminated materials or being bitten by an infected rodent also result in infection. Hantavirus is not spread from person to person. Classic symptoms of disease include fever, fatigue, and muscle aches. Symptoms progress in 4–10 days to cough and shortness of breath.

Measles

The disease measles, also known as rubeola, is contracted by inhalation of infectious droplets expelled as respiratory secretions by an infected individual. The only known reservoir of the measles virus (MeV) is humans. All strains of this virus belong to a single antigenic type and immunity is long lasting following infection.

Fever, malaise anorexia, and respiratory symptoms mimic other respiratory infections, but the appearance of Koplik's spots precedes a rash on the face that proceeds down the body to the soles and palms. Severe complications may occur including a chronic degenerative neurologic disease that occurs many years after a measles infection.

Measles is worldwide, but the success of vaccination programs in developed countries has limited the number of cases of childhood measles, decreasing the prevalence over 90% in Europe. However, there are still sporadic outbreaks, which cause more than 100,000 deaths, especially in patients from developing countries. An eradication program from the World Health Organization initiated in 2001 is promising if the appropriate measures are implemented (Holzmann et al., 2016). This program will not only have to assure the availability of the vaccines to developing countries, but also counteract the anti-vaccination movements that have increase the number of unvaccinated children in high-income countries in the recent years (Whelan, 2016; Dube et al., 2015; Kajetanowicz and Kajetanowicz, 2016).

Varicella

Chickenpox is a highly contagious disease caused by the varicella-zoster virus (VZV). Chickenpox is usually a self-limited disease lasting 4–5 days with fever, malaise, and a generalized vesicular rash of blister-like lesions. The rash covers the body, but it is usually more concentrated on the face, scalp, and trunk. Serious complications including bacterial infections of skin lesions, pneumonia, cerebellar ataxia, and encephalitis may occur, but are rare. Disease is spread by aerosol dissemination of the virus during coughing

and sneezing by an infected person or it may become airborne directly from the skin lesions. Incidence of chickenpox is highest among children 1–6 years of age, but the licensing of a vaccine in 1995 and vaccination requirements for daycare and school children greatly reduced the impact of this virus in the United States in around 75% in a 10-year frame (2000–10) (WHO, 2014).

Following varicella infection, the virus becomes latent in sensory nerve ganglia and may reactivate later in life resulting in shingles. Airborne dispersion from herpes zoster patients may also occur and spread the virus to new varicella outbreaks (Saidel-Odes et al., 2010; Suzuki et al., 2004; Lopez et al., 2008).

Infectious Airborne Bacteria

Unlike viruses that require a host cell, bacteria can colonize and grow on a variety of surfaces and in liquids when physical and nutritional factors are suitable. Therefore, bacteria can be released into the air from a variety of natural and anthropogenic environments. When infectious bacteria are released into the air, they can be readily transported via bioaerosols to susceptible individuals.

Legionella

The first report of Legionnaires' disease followed the outbreak of respiratory illness among American Legion conventioners in Philadelphia in 1976. Currently an estimated 10,000–15,000 cases of Legionnaires' disease are reported in the United States per year. The causative agent, *Legionella pneumophila*, is a vegetative Gram-negative bacterium that is ubiquitous in freshwater environments worldwide. It survives as an intercellular parasite of protozoa thereby resulting in protection for the bacterium while in the environment. Infective aerosols can be transported up to 200 m from the source and can be generated from contaminated water spray devices such as showerheads, evaporative condensers, humidifiers and fountains, and also from cooling towers or waste treatment plants (Blatny et al., 2008, 2011).

Following the inhalation, *L. pneumophila* replicates in host macrophage resulting in severe pneumonia. While *L. pneumophila* accounts for the majority of disease cases caused by this genus, 19 other *Legionella* species are also human pathogens, often causing disease in immunosuppressed patients. *Legionella* bacteria that cannot replicate in the lung are cited as the cause of Pontiac fever, a mild flu-like syndrome. Often these organisms are released in aerosols from whirlpool tubs. Pontiac fever results in many more cases of illness, but fewer deaths; while Legionnaire's disease has a much higher mortality, but lower morbidity.

No human-to-human transmission has been documented. For an outbreak of Legionnaires' disease to occur, a series of events must happen. A reservoir of infectious bacteria must be present, the environmental conditions must be right for the concentration of organisms to increase, the organisms must be infectious and the infectious bacteria must be dispersed resulting in human exposure, organisms must be deposited in the appropriate site in the human host, and the host must be susceptible to infection by the *Legionella*.

Other Gram-Negative Bacteria

Escherichia coli, *Pantoea* (*Enterobacter*) *agglomerans*, *Pseudomonas* spp., and *Acinetobacter* spp. commonly isolated in cow barns, pig houses, and poultry barns are among the airborne Gram-negative bacteria associated with animal facilities that can result in human disease. Special interest has been focused in the spread of antibiotic-resistance genes by these bacteria, not only among livestock, but also to humans. Alarming results have been observed and effective measures should be applied to stop their dispersal (Gandolfi et al., 2011; Gao et al., 2014; Li et al., 2016). Disease-causing Gram-negative bacteria are also dispersed into the air from wastewater treatment plants, vegetable and herb processing, recycling facilities and within hospital facilities.

These organisms can cause a variety of health problems, especially to the young, elderly, and immunocompromised persons.

Endotoxin

Endotoxin is a lipopolysaccharide component of the Gram-negative bacteria cell and is released during active cellular growth and after cell lysis. While it is not an infectious particle and people are exposed to them daily, endotoxin is biologically active material derived from bacteria that can affect many human organ systems and disrupt humoral and cellular host mediation systems. Symptoms of exposure to airborne endotoxin include chest tightness, cough, shortness of breath, fever, and wheezing. Obstruction of airflow and exacerbation of asthma has been related to airborne endotoxin concentrations, and atopic and nonatopic asthma have been associated with endotoxin exposure because of its ability to induce inflammatory reactions. Repeated inhalation exposure has been shown to induce allergen-specific airway inflammation. The organic dust toxic syndrome (ODTS) is an acute inflammatory condition caused by high levels of endotoxin, usually resolves within 48 h, and has a prevalence of more than 20% among farmers. Severity of hypersensitivity pneumonitis (HP) can be increase under the influence of endotoxin exposure (Thorne and Duchaine, 2007).

Airborne endotoxin exposure is a concern in dusty occupational facilities such as cotton processing facilities and agricultural settings, and in industrial environments that utilize water spray components (e.g., machining fluids). Indoor airborne endotoxin is a

concern with humidified mechanical air conditioning systems. The presence of dogs, moisture, and settled dust increase the likelihood of airborne endotoxin in the home. Despite the evidences that high concentrations of endotoxin has over human health, no limits have been established to prevent it and no international standard protocol is available to obtain comparable results (Smets et al., 2016).

Mycobacterium Species

Mycobacterium tuberculosis is recognized for its role as the causative agent of human tuberculosis. Infected individuals can spread pathogenic bacilli when coughing, talking, speaking, laughing, and sneezing. Aerial dissemination of pulmonary tuberculosis was confirmed back in 1959, and recent studies have shown the need for implementing prevention measures to avoid the spread of the disease and ultimately, eradicate it (Riley et al., 1959; Escombe et al., 2007; Fennelly, 2007).

Overcrowding and low-socioeconomic status are often contributing factors to the spread of tuberculosis as individuals are in close association and hygiene conditions are usually poor. The confined spaces of airplane cabins have been implicated in transmissions to passengers and flight crew members. Infectious aerosols resulting from the operation of suctioning instruments during medical treatment, manipulation of tuberculosis ulcers, drainage of necrotic tissue, and exposure during autopsy have also been cited as causes of nosocomial *M. tuberculosis* infections.

Also, nontuberculosis mycobacterial species can be transported via the air and result in disease. Respiratory infection in immunocompromised patients has been associated with members of the *Mycobacterium avium* complex. *Mycobacterium bovis* can also affect humans, especially in low-income countries, and airborne transmission has been suggested as a main form of dispersion (Gannon et al., 2007; Lan et al., 2016). *Mycobacterium leprae* bacilli have been reported from the nose blow of an untreated person with lepromatous Hansen's disease (leprosy), and *Mycobacterium terrae* isolated from a water-damaged building demonstrated inflammatory responses in mouse lung during laboratory experiments.

Gram-Positive Non-Spore-Forming Bacteria

Numerous Gram-positive bacteria are usually disseminated from the skin, oral and nasal surfaces, and hair of humans. This group is more frequently isolated from air samples than Gram-negative bacteria, with *Staphylococcus* being the most common genus of non-endospore-forming Gram-positive bacteria isolated in indoor air samples (Okten and Asan, 2012; Gilbert et al., 2010; Yu et al., 2015). The presence of these cells in the air increases the likelihood of nosocomial infections in healthcare settings. Nosocomial infections by airborne pathogens and with antibiotic-resistant bacteria in hospital environments are transmitted among patients through aerosol dispersal from patients, staff, surfaces, and aspiration from respiratory instrumentation. Airborne dispersal of pathogens is also a concern in home care and assisted living environments.

Additionally, the Gram-positive actinomycetes have been associated with illness in occupants of water-damaged buildings. Often they are associated with fungi that colonize on surfaces and building materials following water intrusion. High concentrations of actinomycetes have been obtained in air samples from wastewater treatment plants, entailing an exposure risk, not only for workers, but for the nearby population (Awad and El Gendy, 2014; Li et al., 2012).

Infectious Airborne Fungi

Fungi are ubiquitous in nature. They utilize organic matter for their metabolism. Depending on the genus, they can readily disperse spores, cellular fragments, or cells into the air. Infectious fungi can cause serious mycoses of the respiratory tract and some are disseminated to the bone and other systems in the body.

Histoplasma capsulatum

Inhalation of spores of the fungus *H. capsulatum* can result in histoplasmosis. This disease is not transmitted from an infected person or animal to someone else but is the result of airborne transport from environmental surfaces and it is the most frequent mycosis in the United States (Cano and Hajjeh, 2001). Histoplasmosis primarily affects a person's lungs, and its symptoms vary greatly. Infected people are generally asymptomatic or they experience mild flu-like symptoms not requiring medical attention. Chronic lung disease resulting from infection with *H. capsulatum* resembles tuberculosis, and can worsen over months or years. The most severe and rarest form of histoplasmosis occurs when it is disseminated involving spreading outside the lungs. If untreated, disseminated histoplasmosis is fatal and has emerged as an opportunistic pathogen in HIV (human immunodeficiency virus) positive people (Cano and Hajjeh, 2001).

H. capsulatum is a dimorphic fungus with a mold (mycelial phase) when it is growing in soil at ambient temperatures, and a yeast phase after being inhaled by humans or animals. It has a global distribution in temperate zones, usually closely to rivers (Baumgardner, 2012; Chakrabarti and Slavin, 2011). The mold spores are either microconidia ranging from 2 to 5 µm in diameter or macroconidia ranging from 8 to 15 µm. The yeast cells of *H. capsulatum* are oval to round in shape with diameters ranging from 1 to 5 µm.

Coccidioides immitis

Inhalation of airborne *C. immitis* arthroconidia may result in the disease coccidioidomycosis (also called San Joaquin Valley fever). A cryptic species, *Coccidioides posadasii*, presents a different distribution and characteristics, but it can also cause coccidioidomycosis and its dispersion through the airway route (Welsh et al., 2012). Within 48–72 h after inhalation and deposition in the lung, the arthroconidia change into spherules and develop numerous endospores. When spherules rupture, they release endospores which have the capacity to develop into a mature spherule.

Approximately 40% of those who become infected are symptomatic with flu-like illness with fever, cough, headaches, rash, and myalgia. Some individuals fail to recover and suffer chronic pulmonary infection. It accounts for 29% of pneumonia cases in endemic areas (Baumgardner, 2012). Around 5% will develop widespread disseminated infection that may affect the soft tissues, joints and bone, or meninges (Welsh et al., 2012). Coccidioidomycosis meningitis may lead to permanent neurologic damage. The immunocompromised and HIV-infected persons suffer severe pulmonary conditions and diffuse lung disease.

C. immitis grows in the soil of semiarid areas. It is primarily found in the Lower Sonoran life zone and is endemic in the southwestern United States; it is also found in parts of Mexico and South America. Exposure to airborne arthrospores occurs after disturbance of contaminated soil by humans or natural disasters (e.g., dust storms and earthquakes). Association with dust storms has been well documented, with significant outbreaks following a dust storm, with a marked seasonality during the drier and dustier months of the year (Griffin, 2007; Goudie, 2014). Persons in areas with endemic disease who have occupations exposing them to dust (e.g., construction or agricultural workers, and archeologists) are at risk. African-Americans and Asians, pregnant women during the third trimester, and immunocompromised persons have a higher risk than others.

Blastomyces dermatitidis

Blastomycosis is an infection caused by the dimorphic fungus *B. dermatitidis*. This fungus grows in moist soil that is enriched with decomposing organic debris, and it is endemic in parts of the southcentral, southeastern, and mid-western United States. It is also present in some areas of Central and South America and parts of Africa and India. Exposure is via the inhalation of airborne spores, generally after disturbance of contaminated soil. Generally, individuals who frequent wooded areas with endemic disease (e.g., farmers, forestry workers, hunters, and campers) are the most exposed ones.

There are <1 to 100 per 100,000 population in areas with endemic disease. The infection may be asymptomatic or result in a flu-like illness with fever, chills, productive cough, myalgia, arthralgia, and pleuritic chest pain (Baumgardner, 2012). However, some infected individuals fail to recover and develop chronic pulmonary infection and permanent lung damage. Other individuals develop widespread disseminated infection that may involve the skin, bones, and genitourinary tract, and occasionally the meninges of the brain are affected. The mortality rate for blastomycosis is approximately 5%.

Cryptococcus neoformans

C. neoformans var. *neoformans* causes most cryptococcal infections in humans. Infection with this yeast-like fungus can cause disease in apparently immunocompetent and immunocompromised persons, but most people do not get sick with cryptococcosis. Patients with T-cell deficiencies are the most susceptible to infection, and in the United States 85% of cases occur in HIV-infected persons. While the initial pulmonary infection is usually asymptomatic, cryptococcosis can cause serious symptoms of brain and spinal cord disease, such as headaches, dizziness, sleepiness, and confusion. Disseminated infection, especially meningoencephalitis, occurs in most patients.

C. neoformans var. *neoformans* is found worldwide, and its habitat includes debris around pigeon roosts and soil contaminated with decaying pigeon or chicken droppings. Exposure generally occurs when dried bird droppings are disturbed and dust containing *Cryptococcus* disperses in the air. The exact nature of the infectious particles of *C. neoformans* is not known, but they are likely to be dehydrated yeast cells or basidiospores of the appropriate size range to be deposited in the lungs. Once in the lung, the yeast cells become rehydrated and acquire the characteristic polysaccharide capsule. Virulence of this organism is associated with the ability to produce the large capsule and shed great amounts of capsular material into the body fluids of the host.

Aspergillus

Aspergillosis is an invasive pulmonary infection with fever, cough, and chest pain. A localized pulmonary infection occurs for immunocompetent persons who have an underlying lung disease. The fungus infection may disseminate to other organs, including brain, skin, and bone. Exposure may also result in allergic sinusitis and allergic bronchopulmonary disease. A variety of *Aspergillus* species have been implicated.

Aspergillus fumigatus and *Aspergillus flavus* most often have been cited, but *Aspergillus terreus*, *Aspergillus nidulans*, and *Aspergillus niger* have also been associated with the disease. These fungi are ubiquitous in the environment, and their conidia (spores) are disseminated from soil, compost piles and other decomposing plant matter, household dust, building materials, and ornamental plants. Among with other genera (*Cladosporium*, *Penicillium* or *Alternaria*), *Aspergillus* is one of the most frequent fungi isolated from air samples, both in indoor and outdoor environments (Mahieu et al., 2000; Cao et al., 2014; Hwang et al., 2016; Oberle et al., 2015; Oh et al., 2014; Grishkan et al., 2012). Water-damaged buildings can also be a source for exposure, and infections have been

associated with dust exposure during building renovation or construction. To decrease workers and nearby population exposure to high levels of *Aspergillus* spores, certain construction works can be restricted to cooler seasons, which seem to influence the growth of the fungus (Pilmis et al., 2016).

Airborne Bioterrorism

The threat of purposeful transmission of airborne pathogenic microorganisms and microbial toxins as weapons of mass destruction (WMD) has increased the awareness of the importance of bioaerosols. The Centers for Disease Control and Prevention and the Department of Health and Human Services have listed several pathogenic microorganisms as select agents. Of these, *Francisella tularensis*, *Yersinia pestis*, *Bacillus anthracis*, and *Variola virus*, the causative agents of tularemia, plague, anthrax, and smallpox, respectively, are ones that can be dispersed via aerosol and, therefore, are a concern for inhalation infection. Moreover, availability of new technologies, such as genetic engineering, may provide the tools to modify innocuous microorganisms or the transmission routes of other pathogens, involving a higher biosafety risk for the population (MacIntyre, 2015). Continued researches and awareness by public health professionals are needed to recognize these diseases and minimize the risk of exposure of the population. For example, the uses of biosensors to detect airborne pathogens are being developed and installed in official buildings and strategic sites, that allow a rapid detection and intervention (Fronczek and Yoon, 2015).

Glossary

Cladocerans These small crustaceans dominate the biomass of zooplankton in shallow eutrophic lakes. They graze on phytoplankton by filtering water and can rapidly build up their populations by parthenogenesis.

Copepods Small crustaceans ranging in size from 0.2 to 10 mm that form the bulk of metazooplankton biomass of large lakes and the sea. Their complex life cycles involve six naupliar and five copepodite (larval) stages that require, depending on temperature and intrinsic timing, a few weeks to a year to complete.

Euphausiids A class of shrimp-like zooplankton ranging in size from 1 to 6 cm that are major grazers of shelf and open-ocean blooms.

Neritic The relatively shallow part of the ocean extending from the low-tide mark to the edge of the continental shelf at c. 200 m depth.

Nutricline An abrupt gradient in nutrient concentrations at the bottom of the nutrient-impooverished mixed layer.

Phytoplankton Unicellular algae belonging to many different lineages that inhabit the surface layer of lakes and oceans and grow by converting dissolved plant nutrients taken up from their surroundings into biomass by means of photosynthesis, which requires adequate light energy and the green pigment chlorophyll.

Protists Unicellular eukaryotic organisms including autotrophic, mixotrophic and heterotrophic taxa from many different lineages.

Zooplankton The collective term for planktonic grazers that can migrate vertically but are too small to swim against ocean currents. They include larger multicellular organisms such as copepods, cladocerans and their predators as well as smaller unicellular protozoa.

Abbreviations

ASP	Amnesic shellfish poisoning
CFP	Ciguatera fish poisoning
DMS	Dimethylsulfide
DMSP	Dimethylsulfoniopropionate
HABs	Harmful algal blooms
HNLC	High-nutrient, low-chlorophyll
PCD	Programmed cell death
PSP	Paralytic shellfish poisoning
SML	Surface mixed layer

Defining Statement

Dense aggregations of phytoplankton cells of one or more species are loosely referred to as algal blooms. They play a central role in the ecology and biogeochemistry of all water bodies from ponds to the ocean, but a mechanistic understanding of the factors leading to the rise and fall of blooms is still lacking.

[☆]*Change History*: September 2018. Philipp Assmy, Victor Smetacek, Marina Montresor and Maria I. Ferrante updated the text, references and figures. This is an update of Assmy, P., Smetacek, V., 2009. Algal blooms. In: Schaechter, M. (Ed.), *Encyclopedia of Microbiology*, third ed. Academic Press, pp. 27–41.

This article is an update of P. Assmy, V. Smetacek, Algal Blooms, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 27–41.

Introduction

'Algal bloom' is a term of convenience applied to an outbreak of phytoplankton cells well above the average for a given region or water body. Blooms show up as peaks in the annual cycle of phytoplankton biomass and chlorophyll concentrations. They are ephemeral phenomena that arise when growth rates of one or more species of the phytoplankton assemblage exceed their mortality rates. As a result, cells of these species accumulate in the water column until their growth is checked by resource depletion, generally a nutrient such as phosphorus, reactive nitrogen, or iron. The magnitude of the bloom peak is determined by the nutrient concentrations prior to outbreak of the bloom. Since all phytoplankton contain chlorophyll *a*, which is easily assessed by a range of methods, the size of a bloom is conveniently expressed in units of chlorophyll. In productive water masses with high-nutrient availability, such as eutrophic lakes and coastal seas, chlorophyll concentrations at bloom peaks can reach $>20 \text{ mg Chl m}^{-3}$, but over much of the ocean tenfold lower values are also commonly referred to as blooms because their concentrations again are five- to tenfold higher than the concentrations prevailing there over much of the year.

Phytoplankton blooms develop in the surface mixed layer (SML), so the total biomass or standing stock of a bloom is expressed as the concentration (cell numbers or biomass m^{-3}) multiplied by the depth of the mixed layer (cell numbers or biomass m^{-2}). The latter varies from less than a few meters in lakes to tens of meters in the ocean, so standing stocks of blooms in both regions are broadly similar because the higher concentrations of algae generally found in shallower mixed layers are compensated by the greater depth of the surface layer where concentrations are lower. It is the standing stock of the bloom that determines how much carbon is fixed per unit area and hence how much food is available to the larger organisms of higher trophic levels and to the microbes and animals (benthos) of the underlying sediments. It follows that the highest standing stocks (largest blooms) develop in SMLs of intermediate depths.

Algal blooms are short-lived phenomena superimposed on the ubiquitous microbial food web, which is the characteristic pelagic ecosystem prevailing in the surface layer of most of the oceans and large lakes (Fig. 1). The system maintains itself by recycling regenerated nutrients (ammonia, phosphate, and iron) between phytoplankton, comprising $<2 \mu\text{m}$ solitary cyanobacteria and small ($<10 \mu\text{m}$) autotrophic flagellates, and heterotrophs, comprising bacteria, their nanoflagellate grazers, and larger protozoa in particular ciliates and dinoflagellates that feed mainly on the eukaryotic components of the food web. They in turn are grazed by copepods and other suspension-feeding zooplankton. Algal biomass is generally $<20 \text{ mg Chl m}^{-2}$, that is, concentrations of $<2 \text{ mg Chl m}^{-3}$ and $<0.5 \text{ mg Chl m}^{-3}$ in coastal and open-ocean regimes, or eutrophic and oligotrophic lakes, respectively. Heterotrophic biomass is generally several fold that of the autotrophs. The opposite situation prevails during blooms: additional or new nutrients, generally in the form of nitrate, are introduced by admixture of nutrient-rich water, which disrupts the quasi-steady state of the microbial food web. The microbial community also profits from the new nutrients, but the bulk of the biomass increase is due to larger phytoplankton inaccessible to smaller grazers. These are the bloom-forming species.

Fig. 1 A schematic representation of the relationship between seasonality of the microbial network (regenerating system) and superimposed blooms. The latter are followed by sedimentation pulses. DOM, dissolved organic matter. Modified by Christine Klaas from Smetacek, V., Scharek, R., Nöthig, E.M., 1990. Seasonal and regional variation in the pelagial and its relationship to the life history cycle of krill. In: Kerry, K.R., Hempel, G. (Eds.), *Antarctic Ecosystems: Ecological Change and Conservation*, first ed. Berlin, Heidelberg: Springer. pp. 103–114. (© Christine Klaas).

In the following we first deal with the so-called bottom-up factors that influence bloom formation, i.e., the physical and chemical properties of the environment. After an overview of the major genera and species contributing to blooms, we deal with the top-down factors – i.e., viruses, parasites, and grazers – that kill phytoplankton cells. The various types of algal blooms – recurrent and sporadic – are discussed followed by a brief account of harmful algal blooms (HABs). We conclude with some future research avenues that need to be explored to further our mechanistic understanding of the rise and fall of algal blooms.

Physical Environment of Blooms

The depth of the SML is generally determined by wind mixing, which in turn is a function of wind force and fetch, which is why the SML is shallowest in small, protected lakes and deepest in the open ocean. The density difference between surface and deeper layers constrains the depth of mixing because the greater the gradient the more energy required to mix across it. Generally, temperature determines density, so the SML is at its shallowest during the summer and in low latitudes. The steep density gradient between the warm SML and the underlying colder water is known as the thermocline. Exceptions are found in estuaries, brackish seas, and at the sea-ice edge during melting where the vertical salinity gradient has a greater effect than temperature in constraining depth of the SML. Here the boundary between the fresher SML and the saltier underlying water is known as the halocline. Pycnocline is the collective term for a density gradient whether caused by temperature, salinity or both.

The depth and rate of vertical mixing of the SML is of critical importance in bloom formation because it determines the light climate experienced by the phytoplankton suspended in it. Light intensity decreases exponentially with depth because light is absorbed by water and converted into heat. Suspended particles and some classes of dissolved organic matter such as humic acids also absorb light or scatter it, contributing to attenuation of light intensity with depth. In the clear blue water of the open ocean, living phytoplankton are the major light-absorbing particles because detritus plays a minor role and most protozoa and zooplankton are transparent to avoid visual predators. At the other extreme, in the green waters of turbid, shallow lakes and tidally mixed shallow seas, suspended particles (detritus and lithogenic particles) scatter and absorb a far greater percentage (>90%) of incoming light than the phytoplankton. So with increasing depth and turbidity of the SML, the light climate experienced by the phytoplankton population as a whole declines.

Net growth of an algal cell occurs only when carbon fixed by photosynthesis exceeds remineralization by respiration. The light intensity at which the two opposing processes balance each other is termed as the compensation light intensity and is in the order of 0.1% of incoming radiation at the surface. Its location in the water column sets the lower boundary of the euphotic zone within which net growth occurs. The depth of the euphotic zone can range from decimeters to meters at low solar angles (winter of high latitudes) and in highly turbid or ice-covered waters, to >50 m in the open ocean. The relationship between the depths of the euphotic zone and the SML determines the rate of bloom growth. If the SML is much deeper, then loss processes outweigh gains by photosynthesis, and phytoplankton biomass cannot increase. In the reverse case, given the presence of adequate nutrients, growth can be sufficiently rapid to attain bloom proportions.

Multi-year satellite records from the Subarctic Atlantic have now challenged the traditional view that blooms are caused by enhanced growth rates in response to improved light climate, rising temperatures and increased stratification. The satellite record showed that bloom initiation coincides with maximum mixed layer depth in winter despite the fact phytoplankton instantaneous growth rates (μ) are minimal in winter. This apparent discrepancy can be explained by decoupling of phytoplankton growth and mortality rates during deep winter mixing. Phytoplankton cells and their grazers are diluted thus lowering encounter rates between predator and prey and decoupling net population growth rates (r) from grazing pressure.

The relationship between SML and euphotic zone depths on bloom development is further rendered complex by the biology of plankton organisms. Thus, phytoplankton can adjust their photosynthetic machinery to work efficiently at low light levels (shade adaptation) of a deepwater column, but the cells suffer damage at high light intensities prevailing closer to the surface if transported there by vertical mixing. A day or two of full sunshine in otherwise cloudy weather can have the same negative effect on shade-adapted cells. Clearly, the species with the highest growth rates will have achieved the optimal trade-off respective to the inherently fluctuating physical environment. On the other hand, loss rates due to pathogens and grazers also vary widely and are generally of much greater importance than respiratory losses of the phytoplankton.

Satellite observations of chlorophyll distribution indicate that the occurrence of algal blooms is related to nutrient rather than light fields. Light limitation of growth rate is restricted to the few winter months at high latitudes and the perennially ice-covered Arctic Ocean. It should be mentioned that the daily photon flux in midsummer at the poles is equivalent to that in the tropics because low solar angle is compensated by the much greater day length. Temperature also has a secondary effect on algal growth rates because of cold adaptation. Unlike land plants that are exposed to widely fluctuating temperatures in the transition phase from dormant to growth seasons, aquatic plants can adapt to a narrow temperature range. Thus, maximum division rates close to the freezing point can be as high as one per day, which is more than half that attained in the tropics. Indeed among the highest rates of primary production measured anywhere ($>10 \text{ g C m}^{-2}$) were recorded in dense blooms developing in the nutrient-rich, shallow SML of the Bering Sea inflow to the Arctic Ocean.

Chemical Environment of Blooms

A prerequisite for the growth of blooms is the availability of essential elements of which the macronutrients phosphorus and reactive nitrogen and the micronutrient iron can limit build-up of blooms. Phytoplankton grow by taking up dissolved nutrients and incorporating them into biomass. Upon cell death, microalgae sink out of the SML, which is thus nutrient-impooverished. Nutrients are supplied back by mixing of deep, nutrient-rich water to the SML. In high and mid latitudes, this is invariably due to

cooling and breakdown of thermal stratification by convective mixing during autumn and winter. In the tropics, upwelling of deeper water due to large-scale lateral advection of the surface layer is the major source of nutrients although runoff from land is also locally important. The passage of storms also mixes nutrients into the SML.

Bloom biomass is limited by the concentration of the nutrient in shortest supply. There is now general consensus that it is phosphate in lakes and some oligotrophic seas (e.g., the Mediterranean), nitrate in iron-rich coastal waters, and iron in the open ocean with the exception of most of the North Atlantic. The concentrations of phosphate and iron are limited by their geochemical properties. Thus, maximum winter concentrations of $\sim 1 \mu\text{mol PO}_4 \text{ L}^{-1}$ seem to be the rule in coastal regions where surface water is in interaction with oxygenated sediments. The corresponding iron concentrations are $>1 \text{ nmol Fe L}^{-1}$, which are well in excess of the P:Fe ratio required by phytoplankton. In contrast, dissolved molecular nitrogen is abundant and can be fixed to reactive forms by cyanobacteria, which results in maintenance of N:P ratios commensurate with the demands of phytoplankton. Because of the extreme insolubility of ferric hydroxide (rust), iron is selectively lost from the SML and becomes the limiting nutrient in land-remote regions. The subarctic North Pacific Ocean and the entire Southern Ocean harbor perennially high concentrations of nitrate and phosphate because of iron limitation of phytoplankton growth. The same is true of the equatorial Pacific. Phytoplankton growth is not continuously iron-limited in the high latitude and equatorial Atlantic presumably due to iron input by dust emanating from the adjacent arid regions.

As unicellular algae are too small to experience shear stress caused by the kinetic energy of water they do not require investment in supporting structures such as carbohydrates to maintain shape and position as do all larger metaphytes. They also have less storage capacity for reserves such as starch or lipids, which, in sessile plants, enable spurt growth at the beginning of the growth season as a means to overgrow competitors for space and light. As a result, the C:N:P ratio of aquatic unicellular organisms resembles that of living cytoplasm and varies $<20\%$ around the global average of 106:16:1. This is known as the Redfield ratio after the scientist who first discovered its relative constancy not only in suspended matter but also in dissolved nutrients in the deep ocean. It should be pointed out that variation in the Redfield ratio within species as a result of adaptation to the growth environment can be as great as between the algal classes.

Major Contributors to Algal Blooms

Of the several thousand phytoplankton species described so far $<5\%$ have been reported to contribute significantly to algal blooms in lakes and oceans, which implies that the ability to form blooms is not an indication of evolutionary success. Many species are widely distributed and regularly contribute to blooms throughout their range, implying that adaptation to a specific set of environmental conditions, such as nutrient ratios or light conditions, is not a prerequisite. Bloom-forming species differ widely from one another in shape, size, and behavior, and – because they belong to different phylogenetic groups – also differ in their pigment composition and biochemistry. Not surprisingly, their blooms also have very different impacts on the ecosystem and biogeochemistry. Their degree of recurrence also varies. Some species bloom every year in the same water body and are an integral part of the seasonal cycle. Others reach bloom proportions only in some years but always in the same season. Yet others form blooms seemingly haphazardly. It is thus not possible to formulate generalizations about bloom-forming species other than that their size (cell diameter, chain length, and colony diameter) tends to be larger than $10 \mu\text{m}$. Since smaller cells tend to have higher growth rates, the ability to grow fast per se cannot be regarded as a prerequisite for bloom formation. Apparently, the ability to withstand attack by pathogens and herbivores by means of larger size and other defenses is hence of greater importance in enabling accumulation of cells. Here, we refer to species differentiated under the microscope, that is, on the basis of their morphology (Fig. 2). In the last decades, the use of molecular approaches coupled with detailed ultrastructural studies showed the presence of several ‘cryptic’ species, i.e., one morpho-species includes genetically distinct species that have exactly the same morphology or differ only for some minor ultrastructural details not visible in light microscopy. This is the case of several important bloom-forming species, which are the better studied ones and which have been often split in a number of species with distinct biogeography. In order to achieve a morphology-independent assessment of species diversity, molecular markers such as the V4 or V9 region of 18S rDNA, are used as barcodes in studies based on the analysis of high-throughput environmental sequencing data. In the following we deal with the bloom-forming species according to taxonomic groupings with some brief notes on their ecology and impact.

Cyanobacteria

This group, formerly known as blue-green algae, are prokaryotes and the progenitors of the chloroplasts of all eukaryotes. They possess essentially the same photosynthetic machinery as the algae but, unlike all algae, some species of cyanobacteria are able to fix molecular nitrogen and channel it into the ecosystem. Another unique property of the larger species is their ability to secrete gas bubbles within minute intracellular vesicles, which renders them positively buoyant and results in formation of conspicuous scum on the surface. Cyanobacteria are present in freshwaters, soil, as endosymbionts in some plants and lichens; in the oceans there are unicellular species (*Synechococcus*, *Prochlorococcus*) and the large filamentous *Trichodesmium* in tropical waters.

Cyanobacteria tend to be rare when fixed nitrogen in the form of nitrate or recycled ammonia is available, but increase their numbers when nitrogen becomes limiting for algal growth but other nutrients, such as phosphate and iron, are still available. This situation invariably arises in the summer months when the N:P ratio, normally at 16:1, reaches its annual minimum. In oxygenated waters, characteristic of most of the ocean as well as oligotrophic deep lakes, this happens because P is recycled more rapidly than N.

Fig. 2 Pictures of prominent bloom-forming species. (a) *Tripos furca*, (b) *Tripos mülleri*, (c) *Noctiluca scintillans*, (d) *Heterocapsa triquetra*, (e) *Scrippsiella trochoidea*, (f) *Prorocentrum minimum*, (g) *Emiliania huxleyi*, (h) *Chaetoceros debilis*, (i) *Chaetoceros curvisetus*, (j) *Chaetoceros socialis*, (k) *Thalassionema nitzschioides*, (l) *Ditylum brightwellii*, (m) *Thalassiosira nordenskiöldii*, (n) *Thalassiosira rotula*, (o) *Pseudo-nitzschia lineola*, (p) *Skeletonema costatum*, (q) *Chrysochromulina polylepis*, (r) *Phaeocystis antarctica* solitary cell, (s) *P. antarctica* compact small colony, and (t) *P. antarctica* large colony. Scale bars = 2 μ m (g), 5 μ m (f), 10 μ m (d, e, m, and p–r), 15 μ m (a), 20 μ m (l, n, o, and s), 30 μ m (b), 50 μ m (h, j, and k), 60 μ m (i), 100 μ m (t), 200 μ m (c). Light micrographs (o), (r), (s), and (t) by Marina Montresor. Scanning electron micrograph (g) was taken by Philipp Assmy. All other light micrographs were taken from the open access repository for plankton-related information PLANKTON*NET (URL: <http://planktonnet.awi.de>) of which (a), (b), (h–k), (m), and (p) were kindly provided by Mona Hoppenrath; (d) and (f) by Regina Hansen; (l) and (n) by Tanya Morozova; (c) by Susanna Knotz; (q) by <http://www.algaebase.org/index.lasso>; and (e) by Alexandra Kraberg.

In shallow eutrophic lakes with suboxic deep water, nitrate is oxidized to N_2 by denitrifying bacteria, which further lowers the N:P ratio. The lowest N:P ratios (<10:1) are found in water bodies overlying anoxic sediments that mobilize not only P but also Fe. It follows that the highest concentrations of cyanobacteria occur in highly eutrophic lakes and ponds.

The most common bloom-forming genera in freshwater, but also brackish seas such as the Baltic, are dealt with next. The ubiquitous genus *Microcystis* builds spherical colonies, but all the other genera occur either as solitary cells (such as the bacteria-sized *Synechococcus* and *Prochlorococcus*) or as chains (*Nodularia*, *Aphanizomenon*, and *Anabaena*). The latter generally form aggregates in the shape of bundles or globular clumps of chains. These species have specialized cells known as heterocysts in which nitrogen is fixed. Cyanobacteria are generally well defended and some species, particularly *Microcystis*, *Anabaena*, and *Nodularia*, sometimes secrete potent toxins. Blooms of these species can pose a serious problem in reservoirs and lakes. The only genus that regularly forms blooms in the ocean is *Trichodesmium*, which grows in sheathed chains (trichomes) that form large aggregates causing a reddish-brown coloration of surface waters in many warm ocean regions.

Diatoms

Most algal blooms in oceans and lakes are dominated by a broad range of species belonging to this group (Fig. 2(h–p)). Diatoms are characterized by their silica shells comprising two half-boxes that fit tightly into one another. The shell surfaces are dotted with minute pores that only allow dissolved substances to enter into the cells. Diatoms can also regulate buoyancy despite the ballast effects of the shell. Shape and size of bloom-forming diatoms vary widely from long-needle-shaped cells up to few millimeters long to small cylindrical cells in long chains. Some species have long silica spines or chitin threads that protrude outward from the cells.

Bloom-forming species are scattered over all diatom lineages (raphid and araphid pennates and various families of centrics) and many genera. Pennate diatoms often dominate algal biomass in sea ice habitats and the microphytobenthos.

The most prominent recurrent feature of the seasonal plankton cycle in temperate and boreal systems is the spring bloom, which is generally dominated by comparatively few species of unrelated genera of diatoms. Typical examples of recurrent bloomers are species of the cosmopolitan diatom genera *Skeletonema*, *Thalassiosira*, and *Chaetoceros* (Fig. 2(h–j, m, n, and p)). *Skeletonema* blooms occur throughout the world with the exception of the polar oceans. They are prominent not only in the spring blooms of the brackish Baltic and the open Atlantic, but also in upwelling blooms of the tropics. *Skeletonema costatum* (Fig. 2(p)), was considered to be a cosmopolitan species but it has been shown that genetically distinct species, which differ in their geographic distribution and seasonal occurrence, share the same gross morphology. A wide variety of species within the genus *Thalassiosira* form blooms worldwide. A few examples include *Thalassiosira antarctica* responsible for blooms in layers underlying sea ice in the Antarctic; *Thalassiosira weissflogii*, *Thalassiosira nordenskiöldii*, and *Thalassiosira rotula* (Fig. 2(m and n)) that contribute to blooms in temperate and boreal areas; and *Thalassiosira partheneia* that builds large (>1 cm diameter) colonies and is found in the upwelling region of northwestern Africa.

The bloom-forming *Chaetoceros* species belong to the subgenus *Hyalochaete* that includes species without chloroplasts in the setae. Most bloom-forming *Chaetoceros* species are capable of converting vegetative cells into thick-walled resting spores that overwinter on the sediment surface in shallow environments, inside the sea ice in the seasonal sea-ice zone, and in the pycnocline in the open ocean. The widespread and consistently high accumulation rates of *Chaetoceros* resting spores in the Southern Ocean throughout the last glacial and their restricted occurrence during the Holocene provide compelling evidence for substantially higher productivity and organic carbon export into the deep ocean during the last glacial and highlight the potential of resting spores as biological proxies for paleoceanography. Three prominent species are *Chaetoceros socialis*, *Chaetoceros debilis*, and *Chaetoceros curvisetus* (Fig. 2(h–j)), with the former two species showing a more polar-to-cold temperate distribution and the latter species a warm temperate distribution. However, also in the genus *Chaetoceros* there are several cases of ‘cryptic diversity’: as an example, it is *C. gelidus* and not *C. socialis* that is abundant in the Arctic and sub-Arctic region. The two species share the same gross morphology and the distinctive globular arrangement of their chains but differ in their genetic profile, the morphology of spores and physiological traits.

The cosmopolitan needle-shaped pennate genus *Pseudo-nitzschia* comprises many species that are difficult to differentiate under the light microscope but some of them can contribute substantially to both open-ocean and coastal blooms. This is one of the best studied diatom genera because it includes several species capable of producing the toxin domoic acid, harmful to humans and other vertebrates. Pennate diatoms have a heterothallic mating system, i.e., cells belong to two different mating types, and this enabled to test reproductive isolation, i.e., the ‘biological species concept’ amongst different cryptic *Pseudo-nitzschia* species.

The needle-shaped, thin-shelled centric genus *Rhizosolenia* commonly forms blooms later in the year. A dense bloom in which the cells were aggregated into mats was reported from the equatorial Pacific where the mats apparently carried out vertical migration between the surface and the nutrient-rich deeper layer. Another widespread species that is common in the summer months is *Ditylum brightwellii* (Fig. 2(l)), which has, however, once formed an almost monospecific spring bloom in the southern North Sea.

Haptophytes (Prymnesiophytes)

This group comprises small flagellates equipped with a prehensile organ, the haptonema, which is used to feed on small particles such as bacteria (Fig. 2(g and q–t)). The cell of these microalgae is surrounded by thin organic scales that, in coccolithophores, bear a mineral layer made of calcium carbonate. These calcareous platelets are called coccoliths. A common characteristic of this group is the copious production of dimethylsulfoniopropionate (DMSP), which is split by an enzyme into volatile dimethylsulfide (DMS) and the noxious acrylic acid. Several functions of the widespread molecule DMSP have been suggested such as a compatible solute in osmoregulation, defense against predators, and as an antioxidant. DMS released from haptophyte blooms is a major global source of sulfur to the atmosphere where it is oxidized to hygroscopic sulfate, which can act as a cloud condensation nucleus. Large amounts of sulfur in the atmosphere result in smaller droplets, that is, whiter clouds that scatter sunlight back into space, thus contributing to cooling. The global significance of haptophyte blooms in cooling the planet is under debate.

The calcareous coccolithophores are second in importance to the diatoms in their contribution to extensive oceanic blooms. These normally arise in the aftermath of the spring diatom bloom and, because of the high reflectance of their coccoliths, are visible from space. The species *Emiliania huxleyi* (Fig. 2(g)) is the most prominent member of this group and forms blooms in both coastal and open-ocean regions. Extensive genome variability within this species seems to explain its ecological success across large latitudinal and environmental gradients. Coccolithophores exhibit highly complex life cycles in which haploid and diploid, stages, some bearing different types of coccoliths, alternate with one another. Blooms of *E. huxleyi* are often terminated by the spread of viral infection within the population. Interestingly, despite its numerical dominance in the surface layer, *E. huxleyi* contributes only a minor fraction of the total calcareous material accumulating in the deep North Atlantic. Less abundant but more heavily calcified coccolithophores like *Calcidiscus leptoporus* contribute the bulk of accumulated calcareous sediments.

Another group of haptophytes involved in extensive blooms in both temperate and polar waters are species of the genus *Phaeocystis*. At least six species have been formally identified worldwide based on morphological and genetic characteristics but some of these taxa may hide cryptic diversity. Three species – *Phaeocystis pouchetii* (Arctic), *Phaeocystis globosa* (temperate and tropical waters), and *Phaeocystis antarctica* (Antarctic, Fig. 2(r–t)) – dominate blooms. These species form colonial stages comprising many hundreds of cells. The life cycle however includes solitary nanoflagellates and coccoid stages. The flagellate stage suffers much higher

Fig. 3 Colonies of *Phaeocystis antarctica* attached to different diatom species (from field material): (a) Spines of *Corethron pennatum*; (b) setae and cell wall of *Chaetoceros dicaeta*; (c) close-up of colony; (d) *Chaetoceros dicaeta*; (e) *Chaetoceros atlanticus*; (f) *Chaetoceros peruvianus*; (g) *Guinardia cylindrus*. Light micrographs by Philipp Assmy.

mortality by both viral infection and protozoan grazing than the colonial one, indicating that colony formation is a defense strategy. The fact that colonies in their early stages are often found attached to the spines of diatoms (e.g., *Chaetoceros*, *Corethron*) also suggests that small colonies are more vulnerable and find protection from protozoan grazing on these large diatoms (Fig. 3). In the North Sea, *P. globosa* tends to attain dominance in the later spring, in the aftermath of the diatom bloom following Si exhaustion. Extensive

blooms dominated by *P. antarctica* are a regular feature of the Ross Sea but, for unknown reasons, are more sporadic elsewhere around Antarctica. On rare occasions dense blooms of the solitary flagellate genera *Chrysochromulina* and *Prymnesium* occur in some regions.

Dinoflagellates

This is an ancient, heterogeneous group comprising autotrophic, mixotrophic and heterotrophic modes of nutrition across a wide range of shapes and sizes (Fig. 2(a–f)). Interestingly, the morphology of photosynthetic and predatory forms does not differ, signifying that their shapes and sizes have not evolved to maximize resource acquisition. The life cycle of several dinoflagellates includes the formation of resting cysts, non-motile stages surrounded by a thick cell wall that can fossilize thus leaving a fingerprint of these organisms over extended time scales. Small-celled dinoflagellates (~10 µm) encased in cellulose armor (e.g., *Prorocentrum*, *Heterocapsa*, *Scrippsiella*) (Fig. 2(d–f)) commonly form blooms in the aftermath of the spring diatom bloom in coastal and shelf areas. Larger, often unarmored forms such as *Gymnodinium* form sporadic blooms not only in the summer months but also in upwelling regions. Spectacular blooms of the heterotrophic bioluminescent *Noctiluca scintillans* (Fig. 2(c)), colored by pigments from their algal food, cause discoloration of large stretches of surface waters mainly in sheltered bays or estuaries. Because of their motility and comparatively large size, some dinoflagellates have been observed to migrate vertically to take up nutrients below a shallow SML. Many species also form dense layers at density discontinuities, which reach the surface along hydrographic fronts where they are highly conspicuous. The standing stocks of such blooms are low, despite their dense concentrations because they are restricted to thin layers.

The largest dinoflagellate blooms in both lakes and the ocean are formed by species of the large, armored genera *Ceratium* and *Tripos* (new genus name for the marine *Ceratium*) during the autumn. For unknown reasons, grazing pressure on this genus is low, suggesting that survival rather than fast growth rates is the major reason for bloom build up over the late summer (Fig. 2(a and b)).

Other Groups

The phototrophic, cosmopolitan ciliate *Mesodinium rubrum* (also known as *Myrionecta rubra*) is an active swimmer that, like dinoflagellates, carries out vertical migration and sometimes forms dense reddish layers at the surface. Its cells are packed with cryptophyte chloroplasts that still carry the cryptophyte nucleus. Blooms of this species are common and have been reported from habitats as diverse as tropical upwelling regions, the inner Baltic and the Arctic shelf. Large blooms of this ciliate tend to be sporadic but patchy blooms occur regularly in the North and Baltic seas in early summer. Other groups reported to contribute significantly to algal blooms are the euglenophytes, cryptophytes, and raphidophytes; their blooms are only of local importance. In lakes, various species of chlorophytes and chrysophytes form blooms under eutrophic conditions.

Pathogens and Grazers of Algal Blooms

The important role of viruses in the sea has only come to light over the past three decades. It is now known that bacterial populations are susceptible to viral infection and that their density is partly regulated by this factor. Less is known about viral infection of algae but blooms of the coccolithophore *Emiliania huxleyi* can be terminated by mass viral infection. It has been demonstrated that viruses can re-shape the antioxidant metabolic network of the host cell during infection, which is essential for a successful viral replication cycle. Viruses of *E. huxleyi* have been detected in copepod guts and can be dispersed by these crustaceans and by their fecal pellets over relatively long distances. An even more effective dispersal can be provided by aerosol, where *E. huxleyi* viruses can remain infective allowing potential dispersal and infectivity over hundreds of kilometers. So far, only few viruses have been found to infect diatoms and dinoflagellates, and the viruses affecting other groups have barely been studied.

Another relevant but poorly known source of mortality for phytoplankton is represented by parasites. They belong to various protistan lineages (e.g., chytrids, various stramenopiles and syndiniales) and many of them share the presence of small flagellates (zoospores) that represent the infective vector. Zoospores can attach themselves to large diatoms and insert feeding tubes through pores in the frustule or between the girdle bands or through the sutures between thecal plates in dinoflagellates. The parasite multiplies while feeding on the microalgal plasma, releasing large numbers of flagellates that can infect other cells. Parasites can be species-specific in prey selection and have the potential to decimate prey populations during blooms. However, the diversity of parasites, their infection modality, and their impact on natural microalgal populations is still largely unexplored.

A wide range of grazers is present in the plankton: puncturing and ingesting protists (i.e., unicellular eukaryotes) that prey on individual microalgal cells and chains, suspension-feeding copepods that select and ingest particles individually, and filter-feeding larger metazooplankton such as euphausiids (krill) that collect particles *en masse* and ingest them indiscriminately. Protistan grazers have growth rates equivalent to their phytoplankton prey and many have evolved techniques to cope with prey sizes as large as or even larger than themselves. Complexity is introduced by the tendency of copepods to selectively feed on protistan grazers of phytoplankton, in particular ciliates and heterotrophic dinoflagellates, which results in a trophic cascade favoring accumulation of algal cells.

Dinoflagellates have evolved the broadest range of feeding techniques: some ingest prey cells up to their own size, others pierce the cell wall and suck out the contents with a feeding appendage known as the peduncle. Several genera of armored dinoflagellates are able to extrude a feeding veil known as the pallium, which can envelope an entire chain of diatoms many times the size of the

Fig. 4 A pallium-feeding dinoflagellate of the genus *Protoperidinium* capturing a pennate chain-forming diatom. Light micrograph by Christine Klaas.

predator and digest it outside the cell wall (Fig. 4). The pallium is retracted after digestion is completed. The entire process of prey capture and pallium retraction lasts for 10–20 min. Again, decimation of algal blooms by dinoflagellates is rarely reported although they have the potential to do so. In all likelihood, the ubiquitous small copepods selectively feed on large heterotrophic protists, which releases grazing pressure on the algae, particularly diatoms.

Metazooplankton, in particular copepods and euphausiids, have complex life cycles involving a range of larval stages that take weeks or months to complete, depending on temperature in opportunistic species, or innate life cycle traits in species with pronounced seasonality. The latter generally have larval stages that overwinter at depth and ascend to the surface in spring. It is widely believed that blooms arise because copepod populations are unable to match their appearance at the surface with the timing of bloom initiation and subsequently gear their population size to the growing bloom. However, this neither explains why other grazers, in particular unicellular herbivores, are unable to suppress blooms, nor does it explain why copepods, if they are indeed so inefficient at utilizing potential food sources, nevertheless manage to maintain the bulk of zooplankton biomass in oceans and oligotrophic lakes.

Mortality is not just caused by an external agent but autocatalytic cell death or apoptosis, analogous to programmed cell death (PCD) in multicellular organisms, does occur in unicellular algae and has already been reported from cyanobacteria, green algae, coccolithophores, dinoflagellates, and diatoms. PCD seems to play a crucial role in the coordinated collapse of phytoplankton blooms but the mechanisms are still not fully understood. This cellular self-destruction process in phytoplankton is triggered by specific environmental stressors that range from cell age, nutrient limitation, high light and/or UV exposure, and reactive oxygen species. Furthermore, it has been shown that lytic viral infection and autocatalytic PCD in the coccolithophore *E. huxleyi* work in tandem.

Mortality or inhibition of growth can be also attributed to allelochemical compounds that are produced by many unicellular microalgae. This is the case of dinoflagellate species of the genus *Alexandrium* that can produce lytic compounds active on a broad range of taxa and it has been hypothesized that those allelochemical compounds may play a role in the formation and maintenance of *Alexandrium* blooms.

It has long been appreciated that, unlike terrestrial vegetation, the bulk of phytoplankton cells are grazed. So, given the diversity of phytoplankton grazers and their potential to overgraze their food, it is indeed surprising that blooms develop at all. However, it should be remembered that only a few of the species present contribute significantly to algal blooms. The other species either do not respond with high growth rates to the advent of favorable conditions or are grazed faster. The conclusion is that understanding bloom dynamics requires basic knowledge of the ecophysiology and species-specific regulatory mechanisms inherent to the bloom formers as well as a deeper understanding of the complex interactions and potential trophic cascades within pelagic food webs. Given the great variability inherent to complex biological systems, it is indeed surprising that there is any degree of recurrence in the annual cycles of species composition and biomass in lakes and the sea.

Recurrent and Sporadic Algal Blooms

Algal blooms can be broadly differentiated into seasonally recurrent and sporadic stages in the annual cycles of plankton of a given water body or region. The former tend to be initiated by seasonal change in the physical regime. At higher latitudes, this is due to

warming and shallowing of the SML by thermal stratification in the spring, and its breakdown by convective mixing during the autumn. The former process improves the light supply of the cells trapped in the SML and the latter reintroduces nutrients lost by sinking from it. Spring and autumn blooms, respectively, are the result of these physical processes (Fig. 1). Blooms are also a regular feature of the upwelling regions of lower latitudes. Long-term data series on the annual cycles of phytoplankton gathered from coastal monitoring sites have provided valuable information on many of the recurrent and sporadic aspects of bloom phenomena outlined in the following paragraphs.

Spring Blooms

Algal blooms, almost always dominated by diatoms, are regular events in the annual cycles of all lakes and coastal oceans that arise when deep mixing during the winter is stopped by the advent of surface stratification during spring (Fig. 1). The timing of the spring bloom is influenced as much by the hydrography of the region as its latitude (light intensity). Thus, spring blooms along the melting ice edge off Greenland occur well before the bloom on the Norwegian shelf 1000 km ($\sim 10^\circ$ latitude) further south. This fact was first noticed in the 1930s and attributed to earlier improvement of the light climate by shallow stratification due to meltwater in the Arctic as compared to the slower establishment of thermal stratification in the stormy northern North Sea. Similarly, blooms start about a month earlier in protected bays and fjords than in the adjacent, open shelf. Turbidity of the water also plays an important role in spring bloom initiation, which occurs much later in the shallow, highly turbid water overlying the tidal mud flats of the German Bight in the southern North Sea than in the clearer water of the tide-free Baltic Sea on the other side of the Danish Peninsula.

The dynamics and composition of the spring bloom varies widely from region to region and also from year to year in the same region, depending on weather conditions, phytoplankton seeding stocks, and prevailing grazing pressure. Thus, when bloom initiation coincides with prolonged calm, sunny weather the bloom peak is reached within 2–3 weeks and is often dominated by only a few diatom species with a high initial seeding stock. At the other extreme, bouts of stormy weather alternating with calmer periods at intervals of a few days can prolong the life time of the bloom by many weeks. In such cases different species dominate biomass across a succession of smaller peaks until nutrient exhaustion is reached and the recycling community established.

The fate of bloom biomass varies depending on its dynamics. In the first case, algal biomass is much higher than that of the heterotrophs and the bloom is terminated by mass sinking of ungrazed cells within a few days. Although the termination phase of blooms is less well studied than the longer growth phase, it is likely that morphology and behavior of the species involved influence the depth and extent to which bloom biomass reaches the sea floor. Thus diatom species tend to sink out quantitatively and the long chains of the spiny genus *Chaetoceros* clump into aggregates, aided by sticky mucilage that entrains other cells in the large, rapidly sinking flocs. Such boom-and-bust-type blooms transfer a large amount of organic matter to the benthos and, when they overlie deeper water, play a significant role in sequestering carbon in the deep water column and sediments.

Consensus is emerging that diatoms are ubiquitous in spring blooms not only because they have high growth rates but also because they are better defended than algae from other groups and hence do not represent an ideal food source. This is at odds with the long-held view of diatoms representing the pastures of the sea. The first and most obvious line of defense constitutes the silica shell that provides mechanical protection against a range of crustacean predators, wards off protistan grazers through long and spiny cell appendages and restricts access to the encased cell for piercing predators and parasites. Although copepods have evolved silica-edged mandibles to crack diatom shells, laboratory experiments and field observations suggest that they prefer protozoa over diatom food. Why this is so is still under debate. One line of explanation suggests that diatoms are nutritionally less valuable than protozoa; another explanation is that diatoms produce substances noxious to copepods, either directly or by reducing their reproductive efficiency. Thus, it has been shown that some diatom species contain enzymes that cleave structural lipids into toxic aldehydes when the shells are crushed. Diatom aldehydes are teratogens, that is, the feeding adults are not affected but egg viability is reduced and the larvae develop malformations. However, only some diatoms possess the enzymes that form aldehydes, and some copepod species are more susceptible to its effect than others. So this is by no means a universal defense but merely one of the weapons in an arsenal of unknown diversity.

The dominant spring bloomers in lakes also tend to be diatoms whereby the centric genera *Melosira* and *Cyclotella* and the pennate species *Asterionella formosa* often dominate. Indeed the latter species has always dominated the spring bloom of Lake Windermere over the past 60 years of continuous observation. In other lakes, its presence fluctuates annually as a result of infection by a parasite.

A pronounced spring bloom, generally dominated by diatoms, was long considered an invariable feature of high and midlatitude seasonal cycles but recent analyses of long-term data indicate otherwise. Thus, a winter–spring bloom of *Skeletonema* used to occur every year over decades in Narragansett Bay, Rhode Island, USA, but is absent since about a decade. Blooms now occur later in the year and have different characteristics to the spring bloom. A similar situation has been reported from San Francisco Bay and could be related to the spread of an invasive filter-feeding bivalve that prevented the bloom from developing. The situation changed when a basin-scale shift in the climate regime led to more input of shelf water to the Bay, which introduced fish predators that checked benthic filter feeders from grazing down the phytoplankton. These examples indicate the complex interactions between bottom-up and top-down factors in shaping the annual cycles of pelagic ecosystems. Long-term data are normally recorded adjacent to research institutes and it is likely that similar variation occurs in deeper, offshore water.

Summing up, there is still a lot we do not understand about the dynamics and fate of spring blooms, particularly at the species level.

Autumn Blooms

Autumn blooms arise when enhanced vertical mixing due to stormy weather and cooling deepens the summer thermocline, thereby introducing new nutrients to the SML (Fig. 1). The biomass and species composition of autumn blooms vary regionally more than those of the spring and they do not occur in all high- and midlatitude oceans. However, much less effort has been invested in their study as compared to spring blooms. In many regions, the autumn bloom is dominated by diatoms that, in the Kiel Bight, can reach their peak as late as mid-November. The species involved are similar to the spring bloom but genetic studies have revealed that the spring *Skeletonema* species is different to the autumn one. Although the characteristic spring genera are present in autumn diatom blooms, the species assemblage tends to be more diverse and includes dinoflagellates and larger ciliates. The latter is probably due to the low number of copepods. Where studied, the bulk of bloom biomass sinks out of the water column.

In regions where dinoflagellates dominate late summer plankton, an early autumn bloom comprising species belonging to this assemblage develops in the initial stages of thermocline erosion. Most prominent are species of the armored genus *Tripes* (= the marine *Ceratium*), in particular the cosmopolitan species *T. muellerii*, *T. fusus*, and *T. furca*. These species are apparently unpalatable although their defense mechanisms, other than their cellulose armor plating, are not known. They have comparatively low growth rates but because their populations accumulate over the summer months, a few divisions over several weeks in the nutrient-rich, autumn water column suffices to build up large biomasses that, in some regions, can rival those of the spring bloom. Growth of their bloom is generally accompanied by declining zooplankton populations, which can be interpreted as a sign of success in the evolutionary arms race.

Tripes blooms regularly occur in many, but not all, coastal environments from the tropics to the Arctic but they are absent around Antarctica. They are apparently terminated by mass cell death followed by sinking, but the sinking rates and the depth to which they sink are not known. Recurrent large *Tripes* blooms regularly lead to anoxic events in the Laholm Bay of southern Sweden. A massive *Tripes muelleri* (formerly *Ceratium tripes*) bloom, which for unknown reasons survived through the winter and sank the following spring, caused widespread anoxia and collapse of the commercial scallop fishery in New York Bight in 1976. This was a one-time event. The same can be said of a massive *Tripes furca* bloom that caused extensive anoxia in the late summer of the North Sea in 1981, but has not occurred since.

Blooms in Upwelling Regions of Low Latitudes

Upwelling of nutrient-rich, cold, deep water occurs seasonally or for longer periods along the western continental margins. The intensity of upwelling varies regionally and over periodic cycles of several years of which the El Nino oscillation is the best known. Dense blooms of diatoms develop in regions with intense upwelling but, because of the high sun angle and rapid warming of the newly replenished SML, algal growth rates are much higher and the bloom peak is reached faster than in spring blooms. Nevertheless, as mentioned in the section on diatoms, much the same diatom genera typical of the midlatitude spring blooms – *Skeletonema*, *Thalassiosira*, *Chaetoceros* – are prominent contributors to biomass, although *Phaeocystis* blooms have only been reported from the Arabian Sea. There is considerable regional and interannual variability in bloom magnitude and composition depending on the intensity of upwelling. Thus, the depth from which the upwelling water emanates can favor either diatom or dinoflagellate blooms. Extensive blooms of *M. rubrum* have also been reported off Peru.

The structure and response of the food web is generally similar to that of spring blooms and again, much the same genera of protozoa and copepods are represented. However, in some upwelling regions, the local sardine-like fishes have developed fine-meshed gill rakers to graze directly on the diatoms, thus short-circuiting the food chain. Upwelling regions harbor large stocks of pelagic fishes indicating that a significant proportion of primary production is retained in the surface pelagic system. However, in regions where upwelling is prolonged over many months, the sinking flux to deeper layers and the underlying sea floor can be substantial. Thus, suboxic conditions can develop in deeper layers over extensive regions. These zones play a crucial role in oceanic nutrient cycles because denitrifying bacteria reduce nitrate to N_2 , thus lowering the N:P ratio. Nitrous oxide (N_2O), which is 300 times more potent as a greenhouse gas than CO_2 , is also formed. In the underlying anoxic sediments methane and hydrogen sulfide are produced, which reach such high concentrations off the Namibian coast that methane bubbles, together with H_2S gas, reach the surface and cause mass death of the local benthos. H_2S is oxidized to elemental sulfur in surface water and the resulting reflective particles can be seen in satellite images. Since global warming steepens the temperature gradient between land and sea, winds are expected to be stronger and upwelling more intense in the future. This will result in greater input of methane and N_2O to the atmosphere further exacerbating global warming.

Sporadic Algal Blooms

Blooms caused by vagaries of the weather acting on hydrography are generally singular and local events. For instance, the passage of storms over stratified, nutrient-poor waters of summer months causes deep mixing and upward transport of nutrients, often resulting in a bloom. Generally the standing stock of these blooms is lower than in seasonal ones, but where motile forms that concentrate their populations along hydrographic gradients (nutricline) are involved, algal densities in thin layers can be very high. Tilting of the pycnocline along hydrographic fronts introduces this layer to the surface resulting in conspicuous stretches of discolored waters. The spatial extent of the discolored patches or streaks ranges from meters in protected bays to many kilometers in the open sea, where they appear as meandering structures in satellite images.

In many regions characterized by surface fronts between water masses with different properties, such as at the entrance of the English Channel, frontal blooms are regular features. Most often dinoflagellates dominate frontal blooms but in estuaries cryptophyte and haptophyte blooms have also been reported.

Harmful Algal Blooms

The term HAB is in common usage to denote proliferations of algal species that have a detrimental effect on human use of lakes and the sea, from drinking water reservoirs, and recreation to aquaculture. Some species produce toxins that reach humans through farmed fishes or molluscs, others harm directly farmed fishes or molluscs, still others produce toxins that reach directly humans through e.g., drinking water, as the toxins produced by freshwater cyanobacteria, and others build-up massive biomass resulting in oxygen depletion in deeper water layers. The spread of artificial fertilizers in agriculture in the second half of the last century led to increased nutrient input to lakes and estuaries, often resulting in algal blooms. Because aquaculture has intensified and spread over the past decades, the incidence of HABs in coastal waters has accordingly increased. Thus, they can be regarded as the aquatic equivalent of terrestrial weeds, which by definition are plants that interfere with human usage of the region. It follows that the number of HABs increases with the intensity and diversification of usage.

Algal blooms caused by nutrient runoff from fertilized fields, referred to as eutrophication, and particularly prominent in lakes, rivers, estuaries, and coastal regions, are being brought under control in Europe and North America by improving agricultural practices and installing sewage treatment plants. In fresh- and brackish waters these blooms are at times constituted by cyanobacteria that can produce potent toxins such as the hepatotoxic microcystin, the neurotoxins anatoxins and saxitoxins, and the cytotoxin cylindrospermopsin, which pose a serious threat for freshwater supplies.

HABs can be produced by phytoplankton species belonging to almost all phylogenetic lineages that differ in size, life history, ecology and produce a range of chemically different toxins or harmful compounds. Here we provide a brief overview of the major types illustrated with some examples.

The occurrence of toxic algal blooms was first brought to the attention of the European public by the notorious bloom of a little-known, small haptophyte flagellate, *Chrysochromulina polylepis*, in May 1988. This species caused extensive fish kills in aquaculture farms along the Swedish and Norwegian coasts. It built up biomass as a dense layer in the pycnocline of the Belt Sea, which moved north with outflowing Baltic water and reached the surface along the Swedish and Norwegian coasts. The bloom of this toxic species was associated with increasing eutrophication at the time but the absence of a similar bloom in subsequent years despite similar weather conditions to those of May 1988 cast doubt on the explanation of a single cause-and-effect relationship.

The dinoflagellates include the greatest number of harmful species some of which produce potent toxins. Many of the species are responsible for fish kills as well as human poisoning via shellfish. Saxitoxin was the first algal toxin to be described; it blocks the sodium channels of neurons causing muscular paralysis and, at high dosage, death. The condition is termed paralytic shellfish poisoning (PSP). Some related genera of dinoflagellates, particularly various species of *Alexandrium*, cause PSP. Not only mussel farms but also wild mussel beds are now closely monitored for toxins, but in the past human deaths due to PSP occurred regularly. A number of other toxic molecules have since been identified in dinoflagellates. Toxins produced by the dinoflagellate *Karenia brevis* escape to the atmosphere and cause respiratory problems in humans. Blooms of this species have been reported for the Gulf of Mexico where they also cause massive fish kills.

Diarrhetic shellfish poisoning is caused by okadaic acid and its derivatives produced by some species of the common dinoflagellate genera *Prorocentrum* and *Dinophysis*. Although not fatal, the toxins can cause severe discomfort to the digestive system. Most of *Dinophysis* species escape detection by standard quantitative methods due to their typically low cell density (10–40 cells L⁻¹). Blooms of unarmoured dinoflagellates of the genus *Cochlodinium* are responsible of massive fishkills in Southeast Asia and North America and their geographic distribution has considerably expanded in the last decades. Dinoflagellates in the genus *Gambierdiscus* that live in close association with macroalgae produce toxins that bioaccumulate in tropical and sub-tropical fishes causing ciguatera fish poisoning (CFP).

Species of the genus *Pseudo-nitzschia* – and a few *Nitzschia* – are the only diatoms known to produce the potent neurotoxin domoic acid, which bioaccumulates in shellfish and causes amnesic shellfish poisoning (ASP). Long-lasting blooms of *Pseudo-nitzschia* species, related to anomalously warm ocean conditions, resulted in the largest outbreak of domoic acid along the North American west coast. Marine mammals have been affected by domoic acid, and clam and crab fisheries experienced prolonged closures.

Ecosystem-disruptive blooms of the small-celled pelagophyte *Aureococcus anophagefferens* appeared suddenly along the northeast coast of the USA in the 1980s and spread southward in subsequent years reaching the Gulf of Mexico. The extremely dense blooms produced unsightly brownish colored water known as brown tides. The increase in light attenuation decreased the biomass and diversity of benthic invertebrates and seagrasses. Copious amounts of mucus produced by the large, centric diatom *Coscinodiscus wailesii* that invaded the North Sea from the North Pacific during the late 1970s caused damage to the fisheries by clogging and tearing fishing nets. However, although this species is now established in the North Sea, blooms comparable to those of the 1970s have not since been reported.

Future Research Avenues

What more we have to investigate in order understand the mechanisms that regulate algal blooms? We have to gain a better understanding of the diversity of species or populations not only in terms of their morphological or genetic diversity but also their physiology, life histories and capability to perceive environmental signals and respond to them. We have to augment our observation capabilities of the plankton community, both in terms of visualizing the organisms in their environment as it is nowadays allowed by cell-imaging technology such as the Imaging FlowCytobot but also extending the temporal scale of observations through long term monitoring programs.

The phenology of bloom-forming species, that is, their mode of gearing to seasonality and hydrography of their environment together with their specific defense strategies and capabilities to send and perceive 'signals', need to be addressed if we are to make headway in understanding the driving forces shaping algal blooms. We conclude by briefly illustrating marine genomic approaches that are shedding light on the biological functioning of unicellular microalgae and on large scale *in situ* experiments that represent a unique opportunity to follow bloom dynamics under natural conditions.

Marine Genomics

Recent advances in genomics hold promise for further understanding of phytoplankton biology. In the last decade, next generation sequencing (NGS) has allowed to move from the expensive and time-consuming methods based on Sanger sequencing to cheaper and faster protocols, coupled with improved bioinformatics pipelines for data managing. This is leading to a steady increase in the number of fully sequenced microalgal genomes (Table 1), including two toxic *Pseudo-nitzschia* species.

The complete genomes of two diatom species, the centric diatom *Thalassiosira pseudonana* and the pennate diatom *Phaeodactylum tricornutum*, have shed light on the evolutionary origins of diatoms and their ecological success. Red algal genes have been found in both the *T. pseudonana* and the *P. tricornutum* genomes providing evidence for a red algal endosymbiont that subsequently became the chloroplast, but the predominance of green algal genes suggests that the green algal endosymbiont preceded the red alga. These findings indicate that diatoms derive from a serial secondary endosymbiosis and not a single event. Diatoms not only inherited genes from their different endosymbionts and the exosymbiont but also a number of bacterial genes through horizontal gene transfer. This unique combination has permitted novel metabolic pathways for these microalgae, e.g., carbon concentrating mechanisms (CCMs), urea cycle, genes encoding the iron storage protein ferritin, which contributed to their ecological success.

With more genomes available, comparative genomics is allowing to appreciate a great level of diversity even within the same phylogenetic groups, revealing very different genetic makeups and indicating that congeneric species can have up to 20% of unique sequences, often with completely unknown function. This will hopefully provide the basis for a mechanistic understanding of the distinctive features at the level of species or populations. In the genome of the recently sequenced polar diatom *Fragilariopsis cylindrus* an unexpectedly high level of allelic divergence has been reported. The differential expression of the divergent alleles under different environmental conditions is probably part of the mechanism that determines the impressive adaptive potential of this species to the extreme and variable environment in which it evolved. Other species are being sequenced for the exploration of specific features, such as lipid accumulation for biotechnological purposes or for understanding the mechanisms that regulate sexual reproduction in diatoms; novel details and insights are emerging from the vast metabolic potential, mechanisms of adaptation, evolutionary history and phylogenetic relationships.

In addition to genome sequencing, transcriptome sequencing (RNA-seq) provides us with complementary tools to explore the gene content of any given species and to approach global gene expression studies in non-model species. The Marine Microbial Eukaryote Transcriptome Sequencing Project (MMETSP) has generated over 650 transcriptome sequences from phytoplankton species, including harmful algae. For species with large and complex genomes, such as dinoflagellates, transcriptomic approaches provide a cost-effective alternative.

Much attention has been devoted to the study of changes in light and nutrient conditions, as these are two of the main bottom-up environmental factors affecting growth and regulating blooms. Transcriptomics datasets exist for different light conditions (day/light cycle, intensity, spectrum), from different growth phases, for cells grown under nutrient starvation, and general metabolic states have been linked to gene modules that co-vary and are similarly coordinated even between distantly related species of a given group.

Trophic relationships appear to be as important in shaping blooms as nutrient and light availability, and phytoplankton cells perceive and actively respond to cues from other organisms. Diffusible cues from zooplankton predators can trigger changes in key traits in phytoplankton. Transcriptomics has provided a few insights into the genetic control of morphological or physiological responses to predators: the increased toxicity of the dinoflagellate *Alexandrium minutum* in the presence of copepods was linked to a very small set of genes changing, while a study of the chain-forming diatom *Skeletonema marinoi* exposed to copepods indicated a stronger response, with activation of stress genes, changes in the lipid and nitrogen metabolism, in cell cycle regulation and in frustule formation. *Alexandrium fundyense* strains have been examined in the presence of the dinoflagellate grazer *Polykrikos kofoidii*, and greater differences have been observed among ungrazed strains than between grazed and ungrazed treatments. This result corroborates other observations suggesting a large variability among strains of the same species and calls for attention when drawing conclusions from studies based on a single strain.

Viral infections are also able to induce profound changes in their host metabolism, as highlighted by studies in infected *Emiliania huxleyi* in which a modulation of host metabolic genes involved in life cycle and of the sphingolipid and antioxidant metabolisms occurs. The role of viruses, bacteria and zooplankton grazing in affecting algal blooms, and the genetic basis for the production of toxins and allelochemicals will need to be explored in dedicated future studies.

In case of toxic algae, transcriptomics has been used to investigate and compare the gene expression of mixotrophic protists under light and dark conditions, and in the presence of prey, and in toxic diatoms to explore responses to changes in nutrients or to chemical cues produced by neighboring cells. Studies of the interactions between toxic *Pseudo-nitzschia* and bacteria have revealed that bacterial compounds can affect diatom growth.

While the number of detected algal genes increases, molecular tools to explore their function are still scarce, although some approaches are routinely applied in a few model species, mostly diatoms. Genetic transformation, possible in a range of species, is exploited to increase, reduce or eliminate a gene product and to look for the phenotypic consequences of the change to infer the role. An exciting new avenue is represented by the application of the recent CRISPR/Cas9 technology, an effective and precise genome editing method that is revolutionizing the way in which genes are manipulated, and that has recently been applied in the diatoms *Phaeodactylum tricornutum* and *Thalassiosira pseudonana*. Most of the unexplained features of phytoplankton, possibly accounting for many of the differences between groups, are likely linked to the vast amount of genes with unknown function. Steadily, functional approaches will allow to assign a role to those that are prominent in specific processes (highly overexpressed in transcriptomics studies, or recurrently appearing in gene models).

Finally, whole genomes of individual species are now being supplemented by metagenomic and metatranscriptomic approaches that aim at circumscribing the genomic variation of natural communities, in case of the former, and the gene expression profile of environmental mRNA in case of the latter. To give some idea of the power of these approaches, the recent TARA Oceans expedition produced and released 116 million eukaryotic transcripts from plankton samples collected from 210 stations during a 2.5-year circumnavigation of the world oceans. The combination of genomic approaches with conventional oceanography will improve our understanding of the factors determining species dominance and succession in phytoplankton blooms and thus help to understand how different algal classes will respond to future climate change.

Large-Scale *In Situ* Experiments

Large-scale *in situ* perturbation experiments are a powerful tool to unravel the complexity of factors enabling bloom formation under natural physical and biological conditions. Their advantage over single-species and microcosm experiments is that they

encompass the entire pelagic community, in particular an intact mortality environment comprising the natural gamut of pathogens, parasites, predators and grazers.

Whole lake experiments in North America and Northern Europe date back to the 1960s and have provided important insights into the limiting nutrient (phosphate) in temperate lakes, eutrophication and toxic bloom remediation, acid rain and trophic cascading effects and lake restoration. These insights have played a key role in the implementation of water management practices to control some of the negative man-made impacts.

In the ocean the equivalent of whole lake experiments are mesoscale fertilization experiments (initial patch size on the order of 25–300 km²) to study the response of the plankton community to nutrient addition and to follow the ensuing biogeochemical fluxes. Large expanses of the open ocean have perennially high macronutrient concentrations (nitrate and phosphate) but low phytoplankton biomass. These are the so-called high-nutrient, low-chlorophyll (HNLC) ocean regions – the subarctic and equatorial Pacific and the Southern Ocean – where phytoplankton growth rates are limited by low iron availability. Thus far 12 artificial ocean iron fertilization (OIF) experiments and three natural iron fertilization studies have been carried out in the HNLC regions. Provided that silicate was in ample supply, the iron-induced blooms were dominated by diatoms. The species composition of the blooming diatoms varied widely and depended on the seeding stock present at the time of fertilization. In some OIF experiments many different species accumulated biomass in about equal proportions, others were dominated by one or a few species with exceptionally high accumulation rates. The smaller phytoplankton of the microbial food web were also stimulated by iron addition but their biomass failed to increase, indicating that the increase in growth rates was compensated by a corresponding increase in mortality rates presumably due to herbivores. This is supported by results from two of the three OIF experiments conducted in high-nutrient, low-chlorophyll, low-silicate waters (HNLC/LSi) of the Southern Ocean where the phytoplankton assemblage was dominated by pico- and nanophytoplankton (largely flagellates) and bloom biomass was kept in check by micro- and mesozooplankton grazers. Thus, while production of the microbial community was largely channelled to higher trophic levels, only the mortality rates of the diatoms were sufficiently low to enable accumulation of biomass. A phosphorous addition experiment carried out in low-nutrient, low-chlorophyll (LNLC) waters of the Eastern Mediterranean elicited a response in the microbial food web that was subsequently transferred to copepods. While all OIF experiments increased the productivity of the plankton community and channelled energy to higher trophic levels, only one OIF experiment could show deep export of the iron-induced diatom bloom. Most OIF experiments were however too short to follow the fate of the iron-induced bloom and thus more research is needed to investigate the effectiveness of OIF experiments for carbon sequestration. The use of ocean pipes to induce artificial upwelling of deep nutrients to nutrient-impooverished surface waters was also put forward as a means for carbon sequestration and sustainable fisheries and aquaculture. Given its size, the ocean seems to be a promising place to cure some of the anthropogenic pressures facing our planet. Research into ocean fertilization approaches is thus highly warranted to improve our understanding of the functioning of pelagic ecosystems on the one hand and to investigate the risks and their potential for ocean sequestration of anthropogenic CO₂ and restoration of dwindling fish stocks on the other.

Glossary

Carriers/transporters Membrane proteins that function to transport substances into or out of the cell through the cytoplasmic membrane.

Fermenter A large growth vessel used to culture microorganisms on a large scale for the production of commercially valuable products.

Immobilized cell A cell attached to a solid support over which substrate is passed and is converted into product.

Metabolic engineering The improvement of cellular activities by manipulation of enzymatic, transport, and regulatory functions of the cell with the application of recombinant DNA technology.

Regulation Processes that control the activities or synthesis of enzymes.

Selection Placing organisms under conditions where the growth of those with a particular genotype will be favored.

Introduction

Amino acids are simple organic compounds that contain one or more amino groups and one or more carboxyl groups. They are the building blocks of peptides, proteins, and they form many complex polymers. There are 20 protein-forming amino acids, all of which except glycine, are optically active and occur as L-enantiomers. Eight of these protein-forming L-amino acids are essential for mammals. There are large demands for amino acids for use in the areas of food and feed additives (Table 1). In 2015 the largest volume of the total amino acid market is occupied by the so-called feed amino acids L-lysine, DL-methionine, L-threonine, and L-tryptophan (Leuchtenberger *et al.*, 2005). Also substantial is the share of the food sector (34%), which is determined essentially by L-glutamate in the form of the flavor-enhancer monosodium glutamate (MSG) and the amino acids L-aspartate and L-phenylalanine, the latter two used as starting materials for the peptide sweetener L-aspartyl L-phenylalanyl methyl ester (Aspartame). Furthermore, amino acids are used in medicine for infusions and as therapeutic agents, they are also required in the chemical industry, such as derivatives in synthetic leathers, surface-active agents, fungicides, and pesticides. The total amino acids made represent a value of more than \$11 billion. The market is growing steadily by about 5–10% per year. The production methods to date are: (1) microbial production, (2) protein hydrolysis, (3) chemical synthesis, and (4) enzymatic synthesis. While chemical synthesis produces a racemic mixture, which may require additional resolution, the other procedures give rise to optically pure L-amino acids.

Microbial Production

Development of Amino Acid Overproducing Strains

Many bacteria are capable of growing on a simple mineral salt medium containing ammonium, phosphate, further salts and glucose as the carbon and energy source. These bacteria are able to synthesize all the compounds necessary for the living cell from these simple nutrients. The dry matter of the bacterial cell consists of about 60% protein, 20% nucleic acids, 10% carbohydrates, and 10% fat. Therefore, the cell must be able to synthesize amino acids rapidly and efficiently. However, as a rule, only as much of the various amino acids as required for growth are synthesized in the bacterial cell, ie, normally, the bacteria do not overproduce and excrete amino acids into the culture medium. The reason is that bacteria have a number of sophisticated regulatory mechanisms, like repression and feedback inhibition through end products, which economically control the overproduction of metabolites.

Thus, classical mutagenesis has been applied to obtain mutants which are able to overproduce a specific amino acid in large amounts. Regulatory strains were obtained by selecting mutants which are resistant to amino acid analogs. Some of these commonly used lysine-, threonine-, and tryptophan-analogs are shown in Table 2. Amino acid analog resistance may be due to derepression of the enzymes involved in the biosynthesis of amino acids or in elimination of the allosteric control of biosynthetic key enzymes. Furthermore, the amount of amino acids synthesized via a branched pathway can be significantly increased by selecting strains auxotrophic for the competing branch. The application of mutagenesis and selection belong to the most important techniques in the development of amino acid overproducing microorganisms, and such mutants still form the basis to apply powerful modern techniques for the development of superior production strains.

[☆]Change History: June 2016. L. Eggeling updated the Sections "Introduction," "L-Glutamate" and "References." He also added the new Table 1.

This is an update of L. Eggeling, H. Sahm, Amino Acid Production, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 150–158.

Table 1 Quantities of selected amino acids produced in 2015 and their major use

Amino acid	Amount (t/a)	Main use
L-Glutamate	4,100,000	Food (MSG, umami)
L-Lysine	2,300,000	Feed
DL-Methionine	1,200,000	Feed
L-Threonine	450,000	Feed
L-Tryptophan	25,000	Feed
L-Aspartate	25,000	Food (Aspartame)
L-Phenylalanine	25,000	Food (Aspartame)

Table 2 Analogues of amino acids used for the selection of L-lysine-, L-threonine-, or L-tryptophan-overproducing strains

Lysine	Threonine	Tryptophan
S-(2-aminoethyl)-L-cysteine (AEC)	α -Amino- β -hydroxyvaleric acid	5-Methyltryptophan
4-Oxalysine	β -Hydroxyisoleucine	4-Methyltryptophan
2,6-Diamino-4-hexenoic acid	N-Lauryl leucine	6-Fluorotryptophan
ε -C-Methoxylysine (2,6-diamino-heptanoic acid)	Norvaline	DL-7-Azatryptophan
δ -Hydroxylysine	N-2-Thienoylmethionine	2-Azatryptophan
α -Chlorocaprolactam	2-Amino-3-methylthiobutyric acid	3-Inolacrylic acid

The current repertoire of strain development includes amongst others: (1) Identification of mutations in classical strains by genome sequencing and their introduction via recombinant DNA techniques into a wild type thus re-building the producer. The reason is that due to undirected mutagenesis disadvantageous mutations might have been accumulated thus reducing growth or speed of sugar conversion. (2) Combination of beneficial mutations of different strains. (3) Gene overexpression to overcome limiting steps. (4) Identification of genes by global (microarray) DNA analysis whose expression correlates with favorable producer strains or fermentation conditions, and the subsequent controlled expression of such genes by genetic means. (5) Application of intracellular flux quantifications using ^{13}C -labeled substrate and ^{13}C -NMR (Niedenführ *et al.*, 2015). (6) Manipulation of export activity to increase the export of amino acid (Bellmann *et al.*, 2001; Dassler *et al.*, 2000). The improvement of cellular activities by directing the enzymatic, transport, and regulatory functions of the cell by use of recombinant DNA technology is now a standard method for obtaining highly productive amino acid producing strains, often based on strains derived by undirected mutagenesis.

L-Glutamic Acid

Following the increasing demand for monosodium glutamate as a flavoring agent in the mid-1950s, a bacterium was isolated in Japan that excreted large quantities of the amino acid L-glutamic acid into the culture medium. This bacterium, *Corynebacterium glutamicum*, is a short, aerobic, Gram-positive rod capable of growing on a simple mineral salt medium with glucose, provided that biotin is also added. A recent monograph collects a great number of the exiting features of *C. glutamicum* leading to amino acid production (Eggeling and Bott, 2005). The production of L-glutamic acid by *C. glutamicum* is maximal at a critical biotin concentration of 0.5 $\mu\text{g/g}$ of dry cells, which is suboptimal for growth. Despite being effectively produced for over 50 years in amounts of currently 4.1 million tons/year the molecular features resulting in L-glutamate excretion are still poorly understood. However, besides biotin limitation a surprising large variety of other treatments also results in L-glutamate excretion, for example, addition of selected detergents like Tween-40, addition of penicillin, use of fatty acid auxotrophic strains, or addition of ethambutol inhibiting arabinogalactan synthesis. Interestingly, all these conditions have more or less in common to target the cell wall. Only recently exciting discoveries were made disclosing new features of *C. glutamicum*, which are linked to cell wall metabolism and L-glutamate production. It was found that *C. glutamicum* possesses a regulatory OdhI protein, together with a eucaryotic-type serine/threonine protein kinase PknG and a phosphatase Ppp, the latter two controlling the phosphorylation status of OdhI (Niebis *et al.*, 2006). Unphosphorylated OdhI inhibits ketoglutarate dehydrogenase activity and the OdhI protein was shown to be necessary for high L-glutamate production. Importantly, Ppp is apparently membrane bound, and the genes controlling the phosphorylation status are adjacent to genes of cell wall synthesis and cell division. Excretion of L-glutamate occurs through the mechanosensitive channel MscCG by passive diffusion (Nakamura *et al.*, 2007). This channel is a homolog of *Escherichia coli* MscS, which serves as an osmotic safety valve in *E. coli* cells. Thus a disordered cell wall influences the osmotic properties enabling L-glutamate efflux, and the regulatory properties of OdhI inhibit ketoglutarate dehydrogenase activity. As a consequence α -oxoglutarate is not further metabolized in the citric acid cycle, but instead preferably converted into L-glutamic acid, whose efflux into the surrounding medium is mediated by MycCG.

In *C. glutamicum*, glucose is mainly metabolized via the glycolytic pathway into C_3 and C_2 fragments. Oxaloacetate is formed via the phosphoenolpyruvate carboxylase and the pyruvate carboxylase (Fig. 1). Thus, *C. glutamicum* has two anaplerotic reactions for

Fig. 1 Biosynthesis of L-glutamic acid in *Corynebacterium glutamicum* using glucose as the carbon source.

the conversion of the C₃-intermediates into oxaloacetate. These reactions are important to always have sufficient oxaloacetate available for condensation with acetyl-CoA and conversion of citrate to α-oxoglutarate. The overall reaction for L-glutamic acid production from D-glucose is:

Thus, the theoretical maximal yield is 1 mol of L-glutamic acid per mol of glucose metabolized. This represents a 100% molar conversion or 81.7% weight conversion of D-glucose to L-glutamic acid.

The L-glutamic acid production is carried out in stirred fermenters up to a size of 500 m³. Provision for cooling, dissolved oxygen measurement, pH measurement and control (usually with ammonium) are required. A temperature between 30 and 35°C and a pH between 7.0 and 8.0 are optimal. The oxygen transfer rate is fairly critical: a deficiency leads to poor glutamate yields, with lactic and succinic acid being formed instead, while an excess causes accumulation of α-oxoglutaric acid. The yield of L-glutamic acid obtained after 2–3 days of incubation is in the order of 60–70% (by weight) of the sugar supplied, and the final concentration is approximately 150 g/L.

L-Lysine

L-Lysine, an amino acid essential for human and animal nutrition, is mainly used as a feed supplement as it is present in most plant proteins only in low concentrations. The wild-type of *C. glutamicum* does not secrete L-lysine into the culture medium. However, excellent high-yield production strains were developed through mutation and selection to antimetabolite resistance together with modern recombinant DNA-techniques (Eggeling and Bott, 2015).

The pathway for the biosynthesis of L-lysine in *C. glutamicum* is illustrated in Fig. 2. A remarkable feature of *C. glutamicum* is its split pathway for the synthesis of L-lysine. At the level of L-2,3,4,5-tetrahydrodipicolinate there are two pathways for the conversion of this precursor into DL-2,6-diaminopimelate. The first enzyme in L-lysine biosynthesis, aspartokinase, is regulated by concerted feedback inhibition by L-threonine and L-lysine. Hence, a homoserine auxotroph or a threonine and methionine double auxotroph of *C. glutamicum* diminishes the intracellular pool of threonine, reduces its marked feedback inhibitory effect on aspartokinase, and promotes lysine overproduction (15–30 g/L). Another effective technique for obtaining L-lysine-producing strains is the selection of regulatory mutants. Growth of *C. glutamicum* is inhibited by the L-lysine analogue aminoethyl-L-cysteine (AEC). This inhibition is

Fig. 2 The split pathway of L-lysine biosynthesis and its regulation in *Corynebacterium glutamicum*; rastered arrows=feedback inhibition.

markedly enhanced by L-threonine, but reversed by L-lysine. This implies that AEC behaves as a false feedback inhibitor of aspartokinase. Some mutants, which are capable of growing in the presence of both AEC and L-threonine, contain an aspartokinase that is insensitive to the concerted feedback inhibition; therefore, L-lysine is overproduced (30–35 g/L). L-Aspartate as the precursor of L-lysine synthesis is formed from oxaloacetate by the anaplerotic reaction of phosphoenolpyruvate and pyruvate carboxylation (Fig. 1). By combined overexpression of aspartokinase and dihydrodipicolinate synthase, L-lysine production can be further increased by 10%. Also the ample supply of NADPH is important which is achieved by an increased flux via the pentose phosphate shunt.

In addition to all steps considered so far, the active export of L-lysine into the culture medium is important. Export is mediated by the specific exporter LysE, a small membrane protein of 25.4 kDa, with five transmembrane spanning helices (Fig. 3). Expression of this exporter is controlled by the LysR-type transcriptional regulator LysG. At elevated intracellular L-lysine concentrations of 35 mM, LysG binds L-lysine and drives expression of the exporter gene to result in an about 20-fold increased induction. As a consequence effective export occurs, enabling high export rates of up to 7 nmol min⁻¹ mg(dry weight)⁻¹. The components driving L-lysine export are the electrochemical proton potential and the chemical concentration gradient of L-lysine. A formal description of the energetic steps during translocation involves symport of the positively charge L-lysine with two OH⁻ (Fig. 3). For the substrate translocation step the pH gradient, and the L-lysine gradient are important, whereas reorientation of the carrier involves the membrane potential. This transporter is a genetic and biochemical system well-designed for excretion purposes:

Fig. 3 Structure of the L-lysine exporter and the putative mechanism of L-lysine excretion in *Corynebacterium glutamicum*.

- It is only induced at elevated intracellular L-lysine concentrations of about 40 mM.
- It has a high K_m value for L-lysine (20 mM) at the internal (cytoplasmic) side, thus preventing efflux under low internal lysine concentration.

In fed-batch culture L-lysine production strains are able to reach under the optimized culture conditions final concentration of at least 170 g/L L-lysine, and the conversion rate relative to sugar used is about 50%. A typical L-lysine production curve is shown in Fig. 4; together with sugar also ammonium has to be fed. The conventional route of lysine down-stream processing is characterized by

- removal of the bacterial cells from the fermentation broth by separation or ultrafiltration,
- absorbing and then collecting lysine in an ion exchange step, and
- crystallizing or spray drying as L-lysine hydrochloride.

An alternative process consists of biomass separation, concentration of the fermentation solution, and filtration of precipitated salts. The liquid product contains up to 50% L-lysine base that is stable enough to be marketed.

Recently, a new concept for lysine production was introduced, in which the entire L-lysine containing fermentation broth is spray dried, and granulated to yield a feed-grade product which contains L-lysine sulfate corresponding to at least 60% of L-lysine hydrochloride. Waste products usually present in the conventional L-lysine hydrochloride manufacture are thus avoided in this process.

In 2015, the price for L-lysine×HCl feed-grade was approximately \$2 per kg. With the benefits provided by modern techniques, such as genetic engineering, and with the potentials of the fermentation technology, additional improvements in the L-lysine process should be realized. L-lysine will continue to be the most attractive feed additive produced by fermentation.

L-Threonine

Until 1986, L-threonine was used mainly for medical purposes, in amino acid infusion solutions, and nutrients. It was manufactured by extraction of protein hydrolyzates or by fermentation using mutants of coryneform bacteria in amounts of some hundred tons per year worldwide. The production strains were developed by empirical classical breeding, introduction of auxotrophies and resistance to threonine analogs such as α -amino- β -hydroxy-valerate, and reached product concentrations up to 20 g L⁻¹. Although the pathway of L-threonine biosynthesis in *E. coli* is much more regulated compared to that in *C. glutamicum*, *E. coli* strains have proved to be superior to *C. glutamicum*. The reason is that *E. coli* has much more effective excretion systems for L-threonine and

Fig. 4 Production of L-lysine with a mutant strain of *Corynebacterium glutamicum*; glucose is fed together with ammonium.

related amino acids, which are not present in *C. glutamicum*. *E. coli* strains with excellent threonine yield and productivity are now available.

In *E. coli* the regulation of the L-aspartate derived amino acids involves several isoenzymes. As shown in Fig. 5 the phosphorylation of L-aspartate, the first reaction in the biosynthetic pathway of L-threonine, is catalyzed by three different aspartokinases. One of these isoenzymes is inhibited by L-threonine and its synthesis is repressed by L-threonine and L-isoleucine. The second aspartokinase isoenzyme is repressed by L-methionine, and the third one is inhibited and repressed by L-lysine. Threonine biosynthesis takes place from aspartate- β -semialdehyde in three enzymatic steps which are encoded in *E. coli* by the *thrABC* operon. The *thrA* gene encodes a bifunctional enzyme with aspartokinase and homoserine dehydrogenase activities. The *thr* operon is under the control of a single promoter, which is bivalently repressed by L-threonine plus L-isoleucine. Additionally, L-threonine synthesis is regulated by feedback inhibition of the homoserine dehydrogenase and homoserine kinase. L-threonine ranks third in production volume among the biotechnologically produced amino acids behind L-lysine and L-glutamic acid.

Based on the synthesis pathway there is a clear focus on two major targets for the design of L-threonine overproducing strains, ie, the prevention of L-isoleucine formation, and stable high-level expression of *thrABC* operon. Therefore, in one of the first steps of strain development chromosomal mutations were introduced to result in an isoleucine leaky strain, which requires L-isoleucine only at low L-threonine concentrations, but at high L-threonine concentrations growth is independent of the addition of L-isoleucine. This mutation has several advantageous consequences: firstly, it prevents an excess formation of the undesired byproduct L-isoleucine; secondly, it prevents the L-isoleucine-dependent premature termination of the *thrABC* transcription. Furthermore, the isoleucine leaky mutation has a positive selection effect on all the cells containing the plasmid with the threonine operon. To obtain very high activities of the *thrABC*-encoding enzymes, this operon was cloned from a strain in which the aspartokinase and homoserine dehydrogenase activities are resistant to L-threonine inhibition and was overexpressed. To prevent the degradation of L-threonine the gene *tdh* was inactivated which encodes the threonine dehydrogenase.

By continuous sugar feeding of such *E. coli* strain L-threonine concentrations of more than 80 g/L are obtained with a conversion yield of about 60%. The recovery of feed-grade L-threonine is rather simple, after the cell mass has been removed from the culture broth by ultrafiltration, the filtrate is concentrated and the amino acid is isolated by crystallization. Currently, L-threonine has been successfully marketed as a feed additive with a worldwide demand of more than 450,000 t per year, with a price of approximately \$3 per kg.

L-Serine

The engineering of an efficient L-serine producing bacterium is a rather recent example where a combination of cellular analyses and engineering methods resulted in a breakthrough in microbial L-serine production (Eggeling, 2007). L-Serine is used as all the other proteinogenic amino acids in infusion solutions but has no major other application. The market is therefore smaller, but the price per kilogram higher than for feed additive amino acids, for example. The current price is approx. \$25/kg. The microbial production of L-serine originally occurred with methanol utilizing organisms taking advantage of the serine hydroxymethyltransferase (SHMT) reaction. In the biosynthesis reaction the SHMT catalyzes the glycine condensation with the C1-unit activated by a tetrahydrofolate

Fig. 5 Regulation of L-threonine biosynthesis in *Escherichia coli*. Only the regulation by L-threonine and L-isoleucine is shown.

derivative (THF) to form L-serine. However, this method suffered from the external addition of glycine and low conversion yields. As will be seen below the SHMT reaction plays a key role in microbial L-serine production. It catalyzes the interconversion of 5,10-methylenetetrahydrofolate+glycine+H₂O=tetrahydrofolate+L-serine, with the interconversion and dissociation of reactants within the same order of magnitude.

Using sugars like glucose as a carbon source L-serine derives directly from glycolysis in just three enzymatic steps (Fig. 6), and a systematic study revealed that besides removing bottlenecks in its synthesis, a major issue of L-serine accumulation is to prevent its degradation. Indeed L-serine has a key position in central metabolism, since as much as 8% of the glucose carbon flux is via L-serine. The reason is, that L-serine besides being incorporated into protein is required for a number of purposes, like synthesis of phospholipids, L-tryptophan, and L-cysteine. Moreover, the SHMT reaction in its biodegradative reaction provides glycine required for purine, protein and heme synthesis, and more importantly, provides the activated C-1 compound 5,10-methylene-THF which in turn can be further converted into 5,10-methenyl-THF, and other activated C-1 units like 10-formyl-THF, 5-formyl-THF, and 5-methyl-THF to serve different demands in metabolism, like 5-methyl-THF for L-methionine synthesis, 5,10-methenyl-THF for D-pantothenate synthesis, or 10-formyl-THF for N-formylmethionyl-tRNA and purine synthesis. It is obvious that only due to the requirement for purine synthesis and provision of tRNA^{fMet} for translation initiation a high L-serine degradative flux via the SHMT reaction occurs.

To derive from the “work horse” of amino acid production, *C. glutamicum*, an L-serine producer a number of steps were undertaken. These were as follows: At first the feedback control of the 3P-glycerate dehydrogenase (PGDH) was removed, which is allosterically controlled by L-serine. Sequence comparisons revealed that the C-term of the *serA*-encoded PGDH represents the domain involved in allosteric control. Therefore, a comprehensive set of truncated *serA* versions was made, with the most prominent mutation being *serA*Δ197, where as much as 197 amino acyl residues from the C-term were deleted and which resulted in an activity almost insensitive to L-serine inhibition but with catalytic activity largely retained (Fig. 6). However, overexpression of the mutant allele *serA*Δ197 in *C. glutamicum* either alone or in combinations with *serC* and *serB* overexpressed did not result in significant L-serine accumulation pointing to an intracellular conversion of L-serine.

Therefore, in the second step, the intracellular fate of L-serine was studied with 13-C labeled L-serine. Tracing of the label revealed that L-serine as an entity is converted to pyruvate and a genomic screen revealed furthermore that an *sdaA*-encoded serine dehydratase is present in *C. glutamicum*, likely to be responsible for degradation. The serine dehydratase contains an [4Fe-4S] cluster involved in the pyridoxal-5'-phosphate independent deamination of L-serine to pyruvate. When the enzyme was deleted and then the *serA*Δ197, *serC* and *serB* genes overexpressed a slight transient L-serine accumulation was observed.

The study with 13-C labeled L-serine also showed that glycine was formed from L-serine added, and this was not surprising considering that there is no preference of the SHMT for the forward or backward reaction. As mentioned, L-serine conversion catalyzed by SHMT serves to provide amongst others activated C-1 units and this cellular demand cannot entirely be bypassed by external metabolite addition. Therefore SHMT is essential. However, the metabolic engineers used a trick to deplete the SHMT activity. As mentioned, the SHMT requires THF for function. Therefore, the *pabAB* and *pabC* genes were deleted, encoding the aminodeoxychorismate synthase and aminodeoxychorismate lyase catalyzing two steps of THF synthesis. SHMT activity and growth of the resulting strain was dependent on THF, or its intermediate p-aminobenzoate.

Thus the strain eventually made was *C. glutamicum* 13032Δ*sdaA*Δ*pabABC* *pserACB*. This is derived from the type strain ATCC13032, deleted of serine dehydratase (*sdaA*), and of the folate synthesis genes (*pabABC*), and overexpressing the three genes

Fig. 6 On the left is shown L-serine synthesis as derived from 3-phosphoglycerate from glycolysis. On the right is shown a series of plasmid constructs and their resulting 3-phosphoglycerate dehydrogenase activity in absence and presence of L-serine.

of the L-serine synthesis pathway (*pserACB*) with the *serA* gene carrying the deletion at its C-term. Under industrial relevant conditions the performance of this strain was demonstrated in a 20-L reactor based on corn steep liquor (CSL) medium. CSL provides amongst others some folate to enable restricted growth and reduced SHMT activity of the strain. The medium contained 35 g L⁻¹ solid CSL plus initially 15 g L⁻¹ glucose, 15 g L⁻¹ fructose and salts. The minimum dissolved oxygen concentration was set to 50% saturation to ensure no oxygen limitation. As can be seen in Fig. 7, inoculation of the reactor with cells enabled growth up to a maximum specific growth rate of 0.25 h⁻¹, which is about 60% that of the wild type. L-Serine formation occurred already from the beginning, suggesting a suitable folate supply in the culture due to CSL, which can be assumed to contain at least traces of this vitamin. The maximum oxygen uptake rate, OUR_{max}, was about 110 mol L⁻¹ h⁻¹, which was present at the end of the logarithmic growth of the culture. The maximal specific productivity was 1.45 mmol g⁻¹ h⁻¹, and the volumetric productivity about 1.4 g L⁻¹ h⁻¹. In this experiment a final concentration of 345 mM L-serine was reached, but significantly higher concentrations can be obtained, and further derivatives of this basic strain have been developed.

Enzymatic Production

L-Aspartic Acid

L-Aspartic acid is industrially produced by an enzymatic process in which aspartase (L-aspartate ammonia lyase EC 4.3.1.1) is used. This enzyme catalyzes the reversible interconversion between L-aspartate and fumarate plus ammonia. The equilibrium constant of the deamination reaction catalyzed by the enzyme is 20 mmol/L at 39°C and 10 mmol/L at 20°C, thus the amination reaction is favored. Aspartase purified from *E. coli* is a tetramer with a molecular weight of 196 kDa and it has a strong requirement for divalent metal ions. As the isolated enzyme is very unstable in solution an immobilized cell system based on *E. coli* cells entrapped in a polyacrylamide gel matrix was developed. Using this system the half-life of the aspartase activity could be increased to 120 days. Immobilization of the cells in κ-carrageenan, resulted in remarkably increased operational stability; thus, a biocatalyst with a half-life of approximately 2 years was obtained (Table 3). In addition, recombinant DNA-techniques helped to improve aspartase-containing strains. A plasmid with the *aspA* gene elevated aspartase formation in *E. coli* approximately 30-fold.

The production of L-aspartate by means of immobilized cells has been industrialized by using a fixed bed reactor system. A continuous process enables automation and efficient control to achieve high conversion rates and yields. A column packed with

^bGA=glutaraldehyde, HA=hexamethylene diamine.

the κ -carrageenan-immobilized cells produces 200 mmol L-aspartate per hour and gram of cells; thus, in a 1-m³ column about 100 t of L-aspartate can be produced in 1 month. In comparison to the microbial amino acid production the advantages of this enzymatic production method are higher product concentration and productivity. Furthermore less by-products are formed; thus, L-aspartic acid can be easily separated from the reaction mixture by crystallization. In recent years the market for L-aspartic acid has increased to approximately 30,000 t per year due to the fact that this amino acid is a precursor for the production of the dipeptide sweetener aspartame (methyl ester of aspartyl-L-phenylalanine).

Future Prospects

For the synthesis of the proteinogenic amino acids microbial fermentation represents the key position among the production methods in the amino acid industry. Due to modern techniques such as genome sequencing, high-throughput screening based on amino acid sensors, DNA chip technology, and metabolomics, further improvement of the microbial processes are constantly achieved. Bottlenecks in the L-amino acid synthesis can be removed by amplification of genes coding for the limiting enzymatic steps. The recent discovery of amino acid secretion carriers opens up an entirely new field for increasing the overproduction of various L-amino acids. Furthermore, a thorough understanding of the various elements and mechanisms controlling the biosynthesis of an amino acid should make it possible to still further influence its production rate in a predictable way.

Glossary

Anthropozoonotic disease A disease that is able to circulate between humans and animals.

Axostyle A large bundle or hollow rod of microtubules that runs down the central axis of the cell, providing structural support. Present in oxymonads and most parabasalids, but of independent origin in the two groups.

Flagellate A unicellular eukaryote that has flagella in the main growth and division phase of the life cycle (trophozoite). Usually refers specifically to heterotrophic eukaryotes.

Giardia A group of intestinal parasites of humans and other vertebrates. Belongs to the taxon Diplomonadida.

Hydrogenosome A form of mitochondrion-related organelle that generates ATP under anaerobic conditions, generating hydrogen gas as a waste product.

Karyomastigont A subcellular complex consisting of a discrete cluster of flagella, with associated cytoskeleton, and a nucleus. The term is also used to refer to some organisms in which the flagellar cluster and nucleus are tightly associated.

Mastigont A subcellular complex consisting of a discrete cluster of flagella and associated cytoskeleton.

Metamonads In its current usage, the group consisting of diplomonads, retortamonads, parabasalids, oxymonads, and their relatives.

Mitosome A small organelle that is homologous to mitochondria, but has no role in generating ATP.

Monophyletic group A group of organisms consisting of an ancestor and all of its descendants. Also known as a clade.

Trichomonas A group of commensal or parasitic flagellates belonging to the taxon Parabasalia. One species, *Trichomonas vaginalis*, infects the human urogenital tract.

Trophozoite Feeding form of a protist (in contrast to other possible lifecycle stages, e.g., cysts).

Undulating membrane In parabasalids, a flap-like connection between the cell membrane and a flagellum that moves with the beating flagellum.

Defining Statement

The article covers the diversity, systematics, life history, cell organization, and evolutionary history of diplomonads, parabasalids, oxymonads, and their relatives. It gives an overview of some important diseases they cause, and symbioses with animals they are involved in. The diverse mitochondrion-related organelles of these anaerobes are also examined.

Introduction

Mitochondria are often considered to be a defining feature of eukaryotic cells; however, it is now clear that a large number of species lack canonical mitochondria. These organisms do not form a single taxonomic group, and they are referred to collectively as 'amitochondriate eukaryotes' or 'amitochondriate protists', though as discussed below, almost all have retained the mitochondrial organelle in a highly modified form. An alternative moniker is 'anaerobic eukaryotes'. These protists belong to a number of different

[☆]*Change History*: February 2019. Alastair G.B. Simpson and Ivan Čepička updated the text and references. This is an update of Simpson, A.G.B., Čepička, I., 2009. Amitochondriate protists (diplomonads, parabasalids and oxymonads). In: Schaechter, M. (Ed.), *Encyclopedia of Microbiology*, third ed. Academic Press, pp. 545–557.

This article is an update of A.G.B. Simpson, I. Čepička, Amitochondriate Protists (Diplomonads, Parabasalids and Oxymonads), *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 545–557

lineages that have independently become adapted to environments where little or no free oxygen is present and the primary energy-generating function of canonical mitochondria – oxidative phosphorylation using oxygen as a terminal electron acceptor – is not feasible.

Instead of mitochondria, almost all well-studied amitochondriate eukaryotes have ‘mitochondrion-related organelles’ (MROs) that are bounded by two membranes but that lack characteristic features of mitochondria, most notably those associated with oxidative phosphorylation. These often-missing features include cristae (infoldings of the inner bounding membrane), most proteins of the tricarboxylic acid (TCA) cycle and of the electron transport chain, and the mitochondrial F_0F_1 ATPase (ATP synthase). In most cases these organelles also lack a genome. Some mitochondrion-like organelles also display positive properties that are not found in canonical mitochondria, such as the production of molecular hydrogen. Since the early 2000s it had been suspected that all living eukaryotes have retained some form of mitochondrion-related organelle, however it was recently shown that the oxymonad *Monocercomonoides* has, most likely, completely discarded the whole organelle (see below).

Amitochondriate/anaerobic organisms are scattered across the eukaryote tree of life, and many have well-established phylogenetic placements within groups that ancestrally have canonical aerobic mitochondria. For example, there are important amitochondriate clades within the heterolobosean amoeboflagellates (Psalteriomonadidae), the amoebozoan amoebae (Archamoebae: pelobionts and entamoebae), and the ciliates (several taxa). There are also amitochondriate fungi and fungi-relatives, the most prominent of which are certain chytrids that inhabit the rumen of ruminant animals, and the microsporidia, which are intracellular parasites. The best-known collection of amitochondriate eukaryotes, however, is the assemblage made up of diplomonads, parabasalids, oxymonads, and their relatives. This group, collectively called Metamonada or ‘metamonads’, is the most diverse in terms of cell organization and life history. These metamonads are the major focus of this article.

Diplomonads, parabasalids, and oxymonads collectively contain a broad range of symbiotic and parasitic species. These include the important human parasites *Trichomonas vaginalis* and *Giardia intestinalis* (Fig. 1). These organisms are also important from an evolutionary point of view. In the past diplomonads and parabasalids have often been proposed as the earliest diverging branches among living eukaryotes. While this idea is now obsolete, the exact phylogenetic placement of Metamonada within the eukaryote tree of life is still not fully resolved (Fig. 2). Of course, their highly modified mitochondrial organelles, and attendant changes in the biology and biochemistry of the rest of the cell, have made them compelling subjects for study by evolutionary cell biologists.

Amitochondriate Protists and Eukaryote Evolution

The mitochondrion was derived from a prokaryotic cell, specifically an α -proteobacterium. At some point, perhaps 1.5–2 billion years ago, this bacterium entered into a symbiotic association with a eukaryotic or ‘proto-eukaryotic’ host cell. The symbiont became a resident of the host cell, and over time, most genes were lost from the symbiont genome. Many of these genes were dispensable in the new environment, and therefore lost entirely, while others were transferred to the host nuclear genome. The protein products of

Fig. 1 Scanning electron micrograph of *Giardia intestinalis*, an amitochondriate eukaryote belonging to the group Diplomonadida and a significant human intestinal parasite. The cells are seen from the ventral face, much of which forms a large, flanged disk that is used for adhesion to the intestinal wall. Several of the flagella are visible (there are eight in total per cell), including two that bear vanes and beat within a ventral channel posterior to the disk. Image courtesy of K. Vickerman.

Fig. 2 Summary view of the eukaryote tree of life, as inferred (mainly) from recent phylogenomic analyses, highlighting the phylogenetic positions of various better-documented amitochondriate/anaerobic protists (red text and arrows). Each red name or arrow represents a separate inferred evolutionary transition to the amitochondriate/anaerobic condition. Metamonada represents the most diverse of these amitochondriate/anaerobic protist groups, and includes all three of the diplomonads, parabasalids and oxymonads discussed further in this article. Polytomies and dashed lines both represent substantial phylogenetic uncertainty. 's.l.' – *sensu lato* (i.e., in the broad sense).

some transferred genes (together with many genes of non-symbiont origin) are now imported back into the organelle via a complex protein import apparatus that evolved to enable this transport. The evolution of this system cemented a total integration of the erstwhile symbiont into the eukaryotic cell as an organelle.

In the 1980s, it was proposed that some of the living groups of amitochondriate eukaryotes lacked mitochondria because they never had them. These taxa might be early branches from the 'main line' of eukaryotic descent that had diverged prior to the acquisition of mitochondria, making them 'primitively amitochondriate'. In groups with a conspicuous mitochondrion-like organelle, this structure was usually interpreted as the result of a different endosymbiosis involving a different prokaryotic symbiont. The general idea of late acquisition of mitochondria seemed to be supported in the late 1980s by molecular phylogenies that placed several groups of amitochondriate protists, including diplomonads and parabasalids (as well as Microsporidia), as the very earliest branches of the eukaryotic tree.

By the end of the last century, however, this 'mitochondria late' hypothesis had been essentially rejected. Studies of species that were proposed to be primitively amitochondriate showed that these organisms did, in fact, contain genes that likely originated from the genome of the α -proteobacterial symbiont. Actual mitochondrion-related organelles have now been found in nearly all of these taxa. In several cases, the products of nucleus-encoded genes of symbiont origin are known to be targeted to mitochondrion-like organelles, further confirming that these organelles do indeed stem from the same endosymbiotic event as canonical mitochondria. Furthermore, it is no longer inferred that amitochondriate organisms such as diplomonads and parabasalids are uniquely early branches on the eukaryotic tree. Under certain circumstances, molecular sequences that have experienced very large amounts of evolutionary change can cluster together artificially in a phylogenetic tree through the phenomenon of 'long-branch attraction'. Fast-evolving sequences are often drawn toward 'outgroup' sequences, which frequently act as 'long branches'. The fast-evolving sequences may thus appear 'deeper' in the phylogenetic tree than they actually belong. Genes from diplomonads and parabasalids, as well as Microsporidia, are often very divergent, and several studies showed that their deep evolutionary positions could be a long-branch attraction artifact. For example, a variety of evidence demonstrates that Microsporidia are actually closely related to true fungi.

Nonetheless, the true phylogenetic placement of diplomonads, parabasalids, and oxymonads is still not fully resolved (except that they are closely related to each other as 'Metamonada' – see below), and is the subject of ongoing research. Metamonads are usually inferred to be related to some or all other 'Excavates', namely

the taxa Discoba and/or Malawimonadida (Fig. 2). Discoba includes Euglenozoa (e.g., *Euglena* and *Trypanosoma*), the heterolobosean amoebae/amoeboflagellates (e.g., *Naegleria*), and jakobid flagellates. Malawimonads are a small group of free-living flagellates. Since both Discoba and Malawimonadida ancestrally have classical mitochondria, this phylogenetic inference further supports that metamonads evolved from fully mitochondriate ancestors.

Systematics

Diplomonads (Diplomonadida) are flagellated cells, most of which share the characteristic feature of having two nuclei and two near-identical clusters of flagella per cell (see Section “Cell Organization”). There are two major subgroups of diplomonads: Giardiinae and Hexamitinae. The Giardiinae (*Giardia*, *Octomitus*) are all parasites or commensals. The best known is *Giardia intestinalis* (synonyms: *G. lamblia*, *G. duodenalis*), which causes a highly prevalent diarrheal disease in humans – giardiasis or ‘beaver fever’ (see Section “Important Pathogenic Species”). The hexamitines (e.g., *Spironucleus*, *Hexamita*, *Trepomonas*) are more diverse and consist of a mixture of free-living, parasitic, and commensal species (Table 1). Some hexamitines (collectively referred to as ‘enteromonads’ e.g., *Enteromonas* and *Trimitus*) instead have a single nucleus and one flagellar cluster per cell, and look somewhat like half of a typical diplomonad cell.

Parabasalids (Parabasalia or Parabasala) are a diverse assemblage, containing a few hundred described species, almost all of which are parasites, commensals, or beneficial symbionts of animals. There are two basic morphological types. Parabasalids of the first type have a single nucleus associated with a single cluster of a few (usually 4–6) flagella. These are mostly relatively small cells (<20 µm), although there are some much larger forms, and they are found in different types of associations with a diversity of animal hosts. There are also a few free-living species. Parabasalids of the second type have dozens to thousands of flagella. These cells are usually large (tens to hundreds of µm) and are found almost exclusively in the hindguts of wood-eating termites and cockroaches, where they act (or are suspected to act) as beneficial symbionts. Traditionally, most of the multiflagellated species were referred to as ‘hypermastigids’ or ‘hypermastigotes’, while the simple forms were referred to as ‘trichomonads’. Molecular phylogenetic studies confirm, however, that neither hypermastigotes nor trichomonads represent monophyletic groups (clades). It is clear

Table 1 Example amitochondriate protists from Metamonada

Group	Subgroup	Example	Comments
Diplomonadida	Giardiinae	<i>Giardia intestinalis</i> ^a	Prevalent human intestinal parasite
	Hexamitinae	<i>Spironucleus salmonicida</i> <i>Hexamita</i> <i>Trepomonas</i> <i>Enteromonas hominis</i>	Virulent parasite of salmonid fish Many free-living Most/all free-living Enteromonad; human commensal (?)
Retortamonadida		<i>Chilomastix mesnili</i>	Human gut commensal/parasite (?)
Caviomonadidae		<i>Caviomonas</i>	Rodent commensal
<i>Carpediemonas</i>		<i>Carpediemonas</i>	Free-living, marine
<i>Dysnectes</i>		<i>Dysnectes</i>	Free-living, marine
<i>Kipferlia</i>		<i>Kipferlia</i>	Free-living, marine
Parabasalia	Trichomonadida	<i>Trichomonas vaginalis</i>	Prevalent human urogenital parasite
		<i>Trichomonas tenax</i>	Commensal (?) of human oral cavity
	Honigbergiellida	<i>Honigbergiella</i>	Commensal of cattle, free-living
	Hypotrichomonadida	<i>Trichomitrus</i>	Commensal of various animals
	Tritrichomonadida	<i>Tritrichomonas suis</i> ^b	Causes spontaneous abortion in cattle
		<i>Histomonas meleagridis</i>	Poultry pathogen (‘blackhead’)
		<i>Dientamoeba fragilis</i>	Amoeba; human gut commensal/parasite (?)
	Cristamonadida	<i>Mixotricha paradoxa</i>	Termite symbiont; with motility symbionts
		<i>Calonympha</i>	Termite symbiont; with many karyomastigonts
	Trichonymphida	<i>Trichonympha</i>	Termite/wood-eating roach symbiont; multiflagellated
Oxymonadida	Spirotrichonympha	<i>Spirotrichonympha</i>	Termite symbiont; multiflagellated
	Lophomonadida	<i>Lophomonas</i>	Cockroach symbiont; multiflagellated
		<i>Monocercomonoides</i>	Small; diverse vertebrate and insect hosts
		<i>Oxymonas</i>	Medium-large; with holdfast and rostellum
		<i>Saccinobacculus</i>	With actively flexing axostyle
		<i>Pyronympha</i>	Large, attaches with holdfast
		<i>Trimastix</i>	Free-living, marine
		<i>Paratrimastix</i>	Free-living, freshwater

^aSynonyms: *Giardia lamblia*, *Giardia duodenalis*.

^bSynonym: *Tritrichomonas foetus*.

that the large multiflagellated forms arose from simpler trichomonad-like ancestors on multiple occasions in the evolutionary history of Parabasalia.

As of 2017, the high-level classification of parabasalids was based on a combination of morphological characters and molecular phylogenies. This system divides parabasalids into eight major taxa: Trichomonadida, Honigbergiellida, Hypotrichomonadida, Tritrichomonadida, Cristamonadida, Spirotrichonymphida, Trichonymphida, and Lophomonadida (with Honigbergiellida and Tritrichomonadida being possibly paraphyletic). The first four of these taxa are mostly small flagellates with 4–6 flagella. Some species are parasites, including the causative agents of human trichomoniasis (*T. vaginalis*) and of several diseases of domestic animals (see Section “Important Pathogenic Species”). Cristamonadida includes often quite large cells with only a few flagella (e.g., *Devescovina*), as well as multiflagellated species (e.g., *Joenia*), some of which have numerous small clusters of flagella, each usually connected to a nucleus (e.g., *Calonympha*). The Trichonymphida are all multiflagellated (e.g., *Trichonympha*), as are the Spirotrichonymphida (e.g., *Spirotrichonympha*). The latter three subgroups are symbionts of wood-eating insects. Lophomonadida contains only two species of *Lophomonas* with small cells and several dozen flagella; both live in cockroaches.

Oxymonads (Oxymonadida) are not immediately related to parabasalids, but share several superficial similarities. They are all commensals or perhaps beneficial symbionts of animals, and they range in morphology from simple species around 10 µm long to elaborate cells up to 200 µm. The moderate-to-large-sized forms, which constitute the bulk of the described species, are found only in wood-eating insects. A few of the largest oxymonads are also multinucleated and multiflagellated, but most species have only one nucleus and four flagella. Examples of oxymonads include the small, simple *Monocercomonoides* and *Blattamonas*, and larger organisms such as *Oxymonas*, *Saccinobaculus*, and *Pyronympha*.

The three groups described above are related to several more obscure lineages of amitochondriate eukaryotes. The immediate relatives of diplomonads include the retortamonads (Retortamonadida) and Caviomonadidae, both of which are usually commensals or parasites of animals, and a series of free-living forms such as *Carpediemonas*, *Dysnectes*, and *Kipferlia*. Retortamonads are divided into two genera: *Retortamonas*, with two flagella, and *Chilomastix*, with four. Caviomonadidae have a single flagellum (in the past, some caviomonads were thought to be ‘enteromonad’ diplomonads—see above). Meanwhile, *Carpediemonas*, *Dysnectes*, *Kipferlia*, and similar taxa are small free-living cells with two flagella, which have been shown to be related to diplomonads and retortamonads mainly through molecular phylogenies (see Fig. 3). A different set of free-living flagellates, *Trimastix* and *Paratrimastix*, turn out to be the closest relatives of oxymonads. Despite their names, *Trimastix* and *Paratrimastix* species have four flagella. We will not consider these obscure lineages in detail here.

Most recent molecular phylogenies demonstrate that the metamonads are monophyletic. Parabasalids and diplomonads (plus the obscure relatives of diplomonads) are almost always now inferred to be closely related to each other. Oxymonads, *Trimastix*, and *Paratrimastix* (collectively Preaxostyla) typically form the immediate sister group of the diplomonad–parabasalid assemblage. Therefore, it is likely that diplomonads, parabasalids, and oxymonads all descended from a common ancestor that already lacked canonical mitochondria (Fig. 3).

Habitats

Amitochondriate eukaryotes are characteristically found in habitats with little free oxygen. Many do not withstand high oxygen levels, but some (including *Giardia* and especially *T. vaginalis*) at least tolerate or even grow in microoxic conditions and are therefore not strict anaerobes.

Free-living amitochondriate protists are frequently reported from highly eutrophic (nutrient-enriched) sites where high levels of microbial activity have depleted the free oxygen. Natural environments for these species include freshwater swamps, many marine sediments, and intertidal mudflats. Similar but artificial environments in which amitochondriate eukaryotes are observed include sewage sludges and waste ponds from certain industrial processes such as sugar refining. Amitochondriate eukaryotes also occur in noneutrophic anoxic water masses, such as those that can form at depth in deep fjords due to poor mixing with surface water. Most free-living forms eat prokaryotes.

Many commensal and parasitic amitochondriate eukaryotes live within the intestinal tracts of animals. *Giardia* in humans is one of the many examples. Some parasites, however, have other sites of infection. The parabasalid *T. vaginalis*, for example, infects the human urogenital system, while a related commensal species, *Trichomonas tenax*, lives in the human mouth. Some species of *Spiroplasma* that infect fish can cause systemic infections that spread to numerous tissues in the host.

Certain large parabasalids and oxymonads are beneficial symbionts of wood-eating insects, namely, many termites and the related wood-eating roach *Cryptocercus*. These symbionts live in the insect’s hindgut, together with a diverse biota of prokaryotes (the hindgut also hosts other protists, such as small parabasalids). The larger species produce cellulases, enzymes that degrade cellulose, a major component of woody plant material. These cellulases, together with those produced by the prokaryotic symbionts, are a significant supplement to the endogenous cellulases produced by the termite, which are most important before the hindgut. Larger parabasalids and oxymonads are able to engulf large particles of wood by phagocytosis, and partially digest them. Under the generally anaerobic conditions of the hindgut some end products of their metabolism (e.g., acetate and other organic acids) can then be absorbed and utilized by the insect for aerobic energy production. Other products of their metabolism are substrates for various prokaryotes, which in turn release products useable by the insect.

Fig. 3 Phylogenetic diagram for Metamonada, inferred from molecular phylogenetic analyses, illustrating the relationships among diplomonads, parabasalids, oxymonads and related minor taxa, as currently understood. Unlabeled branches represent obscure genera not discussed further in the text. Also shown is the current higher systematics of Diplomonadida and Parabasalia, as discussed in the text. The two colors within Parabasalia distinguish small forms (red) from large multiflagellated forms (purple) – see text.

Cell Organization

Diplomonads

Diplomonads are small cells, usually around 10 μm in length and often less. With the exception of the ‘enteromonad’ organisms (see Section “Systematics”), diplomonads have a characteristic ‘doubled’ organization. Each cell has two identical-sized nuclei located alongside each other in the anterior half of the cell (Fig. 4). Associated with each nucleus is a flagellar apparatus consisting of a single cluster of flagella and a series of ‘microtubular roots’ formed by parallel microtubules that originate in association with the basal bodies of the flagella and extend into the cytoplasm in different directions. Each flagellar cluster and associated cytoskeleton is sometimes referred to as a ‘mastigont’, and the complex of the mastigont and its associated nucleus is termed the ‘karyomastigont’. There are usually four flagella per cluster, one of which is directed posteriorly, another of which is generally directed laterally, and the final two may be directed anywhere from laterally to posteriorly (Fig. 4). There are three basic microtubular roots recognized in diplomonads: one that travels posteriorly, usually alongside the posteriorly directed flagellum, and two that pass over the top of and underneath the nucleus respectively, although the last of these roots is absent in *Giardiinae* (see below). The microtubular roots determine much of the basic shape of the cell. In all species except *Giardia* spp. (see below), the two flagellar apparatuses are more-or-less identical to each other, and the cell has a rotational symmetry.

The other conspicuous cell component in many diplomonads is the endoplasmic reticulum, which often forms stacks within the cell. Hexamitine diplomonads may also contain food vacuoles, which tend to lie in the posterior half of the cell. A classical stacked Golgi apparatus is not observed by electron microscopy, although individual vesicles appear in encysting *Giardia* cells (see below), and these are involved in Golgi-like posttranslational modifications of cyst wall proteins. To date, mitochondrion-related organelles have been observed in only a couple of species, and these organelles are tiny compared with canonical mitochondria. In *Giardia*, where the mitochondrion-related organelles are ~ 100 nm in size and are definitively identified as ‘mitosomes’ (see Section “Hydrogenosomes and Mitosomes”, below), they are generally located in the center of the cell, posterior to the nuclei,

Fig. 4 Representative diplomonads. (a). *Hexamita* (Hexamitinae). (b). *Giardia* (Giardiinae) in trophozoite form (seen from the ventral side) and in cyst form. *n* – nucleus (note that the *Giardia* cyst contains four nuclei). Scale bar = 5 μ m for all images.

and between the flagellar apparatuses. In *Spironucleus* the organelles function as unusual hydrogenosomes (see below). There are often conspicuous glycogen granules in the cytoplasm of diplomonads.

As in most flagellate eukaryotes, each flagellar apparatus duplicates prior to mitosis, and the flagellar apparatuses serve as the microtubular organizing centers for the mitotic spindle. Mitosis in diplomonads is ‘semi-open’, meaning that the nuclear envelope remains largely intact, but the spindle microtubules penetrate through holes in the envelope to attach directly to the chromosomes. In diplomonads, of course, there are two nuclei, and each must undergo mitosis before actual cytokinesis (cell division). Like many unicellular eukaryotes, some diplomonad species form cysts that are resistant to chemical insult and/or desiccation (Fig. 4(b)). In some parasitic forms (e.g., *Giardia*), the cyst is the infectious form that is transmitted between hosts.

In hexamitine diplomonads, the two flagellar apparatuses are located apart from each other, usually toward the ‘outside’ of the cell. The nuclei, or at least parts of each nucleus, are located between the two flagellar clusters (Fig. 4(a)). Each posterior flagellum is either associated with an open groove on the cell surface or is enclosed by a tube that opens near the posterior end of the cell. The grooves or tubes are feeding structures where material (e.g., prokaryotic prey) is phagocytosed.

In Giardiinae, the two flagellar apparatuses are located close to each other, more-or-less in the center of the cell, and between the two nuclei (Fig. 4(b)). The proximal part of each flagellum is intracytoplasmic, that is, it runs some distance through the cytoplasm before emerging as a distinct structure surrounded by a flagellar membrane (this arrangement is also seen in some hexamitines, but to a much more limited extent). In particular, one flagellum from each flagellar apparatus runs down the central axis of the cell and emerges only at the extreme posterior end. The other flagella emerge at various locations around the cell. There are no distinct feeding-related structures and the cells do not perform phagocytosis.

The best-known member of Giardiinae is *Giardia*. *Giardia* is unusual among diplomonads because the cell has a superficial bilateral symmetry, rather than rotational symmetry. The ‘ventral’ side of the cell is flattened and the anterior half of the ventral face is shaped into a large, flanged ‘adhesive disk’ that the cell uses to attach to the intestine wall of its host (Figs. 1 and 4(b)). Two of the flagella (one from each flagellar apparatus) lie within a wedge-shaped channel that extends posterior to the disk. These flagella bear vanes (Fig. 1) and beat within the channel during attachment. The exact method by which this parasite attaches to the host epithelium may involve several mechanisms. It has often been assumed that the disk acts like a suction cup. Alternatively, or in complement, contraction within the cytoskeleton that supports the disk may allow the rim of the disk to mechanically grip the intestine wall. The disk flange also appears to be capable of actual adhesion to surfaces.

Parabasalids

As discussed above, there is a wide range of cell complexity in parabasalids. The smaller, simpler cells include *Trichomonas* and the other species in the taxa Trichomonadida, Tritrichomonadida, Honigbergiellida, and Hypotrichomonadida (Fig. 5(a)). These cells almost always have a single nucleus, which is located near the anterior end of the cell. The nucleus is associated with a flagellar apparatus, usually in the form of a single cluster of 4–6 flagella and a cytoskeletal system (i.e., the cell has a single karyomastigont). One flagellum is directed posteriorly while the others are directed anteriorly or laterally. In many species, the posteriorly directed flagellum is unusual in that the flagellar membrane is physically connected to the cell membrane for some of its length. The cell membrane is extended as a flap or broad projection along this zone of attachment (in some cases the attached flagellum is also expanded). This creates a fin-like region that moves with the flagellum as it beats, and is referred to as an ‘undulating membrane’.

There are two main microtubular structures within the parabasalid cell – the pelta and the axostyle – which are both associated with the flagellar basal bodies and the nucleus. The pelta is a sheet of spaced microtubules that curves over the anterior side of the nucleus and gives structure to the anterior end of the cell. The axostyle is a column of microtubules that forms the central supportive axis of the cell, and usually extends from the posterior end of the cell into a point. There are also conspicuous nonmicrotubular

Fig. 5 Representative parabasalids. (a). *Trichomonas vaginalis* (Trichomonadida), a small form. (b). *Spirotrichonympha* (Spirotrichonymphida), a moderately large multiflagellated parabasalid. Scale bar = 5 μm for (a) and 20 μm for (b). B – after Duboscq, O., Grassé, P.-P., 1933. L'appareil parabasal des Flagellés, avec des remarques sur le traphosponge, l'appareil Golgi, les mitochondries et le vacuome. Archives de Zoologie Expérimentale et Générale 73, 381–621.

elements to the cytoskeleton such as the striated 'parabasal fibers' that extend posteriorly from the flagellar apparatus into the cytoplasm. These parabasal fibers are associated with the Golgi apparatus, which is conspicuous and shows the classical 'stacked' organization of membrane sacs. The fibers and the Golgi collectively form the 'parabasal apparatus', which is characteristic for the group (and inspired its name). Some species also have a 'costal fiber' or 'costa', a striated fiber that runs under the cell membrane, in association with the undulating membrane. The costal fibers vary in appearance, and are contractile in some cases. There are a few species (e.g., *Histomonas meleagridis*, *Dientamoeba fragilis*) in which the flagellar apparatus and cytoskeleton are reduced or completely absent; these species are highly variable in shape and usually behave as amoebae.

Simple parabasalids usually phagocytose host cellular debris, prokaryotic cells, and even entire host cells in some cases (*T. vaginalis*). Thus, in addition to endoplasmic reticulum, many cells also contain food vacuoles. The parabasalid mitochondrion-related organelles are referred to as hydrogenosomes (see Section "Hydrogenosomes and Mitosomes"). They are roughly the same size as mitochondria, are quite numerous, and are usually found loosely associated with the axostyle and/or costal fiber. Granules of glycogen also preferentially accumulate in association with the axostyle. Curiously, the formation of cysts seems to be uncommon in parabasalids, though some small forms do produce cysts with a distinct extracellular wall. *Trichomonas vaginalis* and some other species form somewhat resistant 'pseudocysts', which are compact, but lack a cyst wall.

Large parabasalids are quite different in overall appearance. In some species each cell has many individual flagellar apparatus–cytoskeleton complexes, each usually attached to a nucleus (i.e., the cell has dozens to thousands of karyomastigonts). The karyomastigonts may be 'bundled together' by their axostyles. In most species, however, there is a single large nucleus. The numerous flagella are then either organized in a single field near the anterior end of the cell (some cristamonads) or formed into two or more plates (trichonymphids) or rows (spirotrichonymphids) that originate at the anterior end of the cell, and run down most of its length, often in spirals (Fig. 5(b)). The parabasal apparatuses may be aligned to these rows. Cells generally phagocytose objects such as wood particles at their posterior end. Many of the large multiflagellated species are more than 100 μm in length, and some reach 0.5 mm. The complement of cell organelles is similar to that of simple parabasalids, although undulating membranes are absent, and the form of the pelta and axostyle can be modified. The parabasal apparatus may have numerous branches and takes many complex forms.

In parabasalid mitosis, the nuclear envelope does not break down, and the mitotic spindle is formed external to the nucleus, with noncentriolar regions called 'attractophores' serving as the microtubular organizing centers for the spindle. The form of the spindle is distinctive. The attractophores begin mitosis next to each other on one side of the nucleus. Some of the spindle microtubules attach to the chromosomes indirectly through the intact nuclear envelope, while others form a solid rod directly between the attractophores. It is this rod that pushes apart the two attractophores, thereby separating the attached chromosomes.

Some larger parabasalids have substantial numbers of prokaryotic ectosymbionts. One remarkable example is the unusual termite-inhabiting cristomonad *Mixotricha paradoxa*, which has only four flagella, yet is very large – up to 0.5 mm. Most of the cell surface is

covered by several species of epibiotic bacteria, including spirochetes that attach to distinct docking sites on the surface of the parabasalid cell. The spirochetes are motility symbionts, and *Mixotricha* is propelled through its environment by the locomotory action of these attached spirochetes rather than by its own flagella. Prokaryote–eukaryote motility symbiosis is also seen in another cristamonad, *Caduceia*.

Oxymonads

Oxymonads generally have a single nucleus located in the anterior portion of the cell. This nucleus is associated with four flagella arranged as two separated pairs connected by a broad sheetlike microtubular root, the 'preaxostyle'. The preaxostyle is also the site-of-origin of a two-dimensional array of linked microtubules, called the axostyle (Fig. 6), that runs down the longitudinal axis of the cell. This structure is only superficially similar to the axostyle of parabasalids and presumably evolved independently. In the oxymonad *Saccinobaculus* the axostyle is highly motile: active sliding of microtubules within the axostyle causes the structure to flex dramatically, such that the entire cell performs a squirming motion.

In many species, the extreme anterior end of the cell forms a microfibrillar structure called a holdfast. This is used to attach the cell to the gut wall of its host. In some groups this holdfast is located at the end of a long columnar structure supported by microtubules, called the rostellum (Fig. 6(b)). The oxymonad cell contains conspicuous endoplasmic reticulum, while a discrete Golgi apparatus is not observed. Most oxymonads can feed by phagocytosis, and cells of smaller species typically ingest prokaryotes, while larger species may ingest wood particles, as per large parabasalids. Many species have prokaryotic symbionts either as endosymbionts within the cytoplasm or as ectosymbionts that attach to the cell surface, as in some large parabasalids. Some oxymonads are known to produce cysts, which are presumably used in transmission to new hosts.

The smallest oxymonads are less than 10 μm long, while the largest uninucleate forms can be up to 200 μm in length, and may have eight flagella rather than the usual four (*Pyronympha*). A few large species have numerous nuclei and flagella. In these cases, each nucleus within the cell is connected to a cluster of four flagella, in a manner analogous to some cristamonadid parabasalids (see 'Parabasalids').

Hydrogenosomes and Mitosomes

The capabilities of the mitochondrion-related organelles of amitochondriate eukaryotes vary widely, however many can be classified as some variant of one of two types: hydrogenosomes and mitosomes (Fig. 7). Hydrogenosomes were first identified in parabasalids, where they seem to be universal. Similar organelles are also found in some other amitochondriate eukaryotes not considered in detail in this article. These include, among others, anaerobic ciliates, some rumen-dwelling fungi, and some heteroloboseans.

The hydrogenosomes of parabasalids are about the same size as mitochondria and, like mitochondria, are organelles that generate energy for the cell. However, they lack most components of the mitochondrial electron transport chain, they do not have a functioning TCA cycle, and they do not use oxygen as an electron acceptor when generating energy. They do, however, contain

Fig. 6 Representative oxymonads. (a) *Monocercomonoides*, a small free-swimming form. (b). *Oxymonas*, an attached form. Scale bar = 5 μm for (a) and 10 μm for (b).

Mitochondrial remnant organelles of *Giardia* function in iron-sulfur protein maturation. *Nature* 426, 172–175, copyright 2003.

several enzymes that are absent in canonical mitochondria, including Pyruvate:Ferredoxin Oxidoreductase (PFO) and [FeFe] hydrogenase.

The core of hydrogenosomal metabolism is depicted in Fig. 8. Like mitochondria, hydrogenosomes can utilize pyruvate as a primary substrate. Within hydrogenosomes, PFO catalyses the decarboxylation and oxidation of pyruvate, forming acetyl-CoA and carbon dioxide. The electrons lost from pyruvate are accepted by the carrier ferredoxin. CoA is recycled via a succinate-to-succinyl-CoA cycle, releasing acetate as a waste product (via an Acetate:Succinyl CoA Transferase – ASCT) and yielding one ATP molecule by substrate-level phosphorylation (via Succinyl-CoA Synthase – SCS, which is actually an enzyme of the TCA cycle of canonical mitochondria). Oxidized ferredoxin is then recycled by donating electrons to H^+ ions (protons), forming H_2 gas. It is this last reaction that is catalyzed by the enzyme hydrogenase. All the classical hydrogenosomal reactions take place in the matrix of the hydrogenosome, and movement of protons across the inner membrane is not required to generate ATP. However, this partial oxidation yields one ATP per pyruvate molecule, many times lower than the yield in mitochondria with a full TCA cycle and electron transport chain, and using oxygen as the terminal electron acceptor.

The waste products of hydrogenosomal metabolism, acetate and H_2 , can be utilized by some prokaryotes. For example, H_2 is a substrate for many methanogenic Archaea, and methanogens and hydrogenosome-bearing parabasalids coexist in the hindguts of termites. Other hydrogenosome-bearing eukaryotes (e.g., some anaerobic ciliates) harbor endosymbiotic methanogens that reside within the eukaryote's cytoplasm and are usually situated immediately alongside the hydrogenosomes. Others support ectosymbiotic sulfate-reducing proteobacteria.

Another form of mitochondrion-related organelle is the 'mitosome'. Mitosomes have no role in energy generation, even under anaerobic conditions. The extremely small (~100 nm) mitochondrion-related organelles of the diplomonad *Giardia* (Fig. 7(b)) are identified as mitosomes. Organelles classed as mitosomes are also found in Microsporidia (Fungi, *sensu lato*) and *Entamoeba* (Archamoebae), neither of which is closely related to diplomonads and parabasalids (see Fig. 2).

Canonical mitochondria perform several important functions in eukaryotic cells that are not directly related to ATP synthesis, opening the possibility that amitochondriate protists could rely on their mitochondrion-related organelles primarily for one or more of these other functions. One such process that is performed by canonical mitochondria is the synthesis of iron-sulfur clusters, which are embedded in the active sites of various enzymes involved in electron transfer reactions. Proteins from the mitochondrial iron-sulfur cluster synthesis pathway (ISC) have in fact been localized to the mitosome of *Giardia*, and their activity has been demonstrated *in vitro*. This indicates that this mitochondrial function is indeed retained by this highly reduced organelle. Iron-sulfur cluster synthesis is also a known function of *Trichomonas* hydrogenosomes. Interestingly, it appears that the mitosomes of *Entamoeba* do not harbor the ISC pathway, demonstrating that there is no universal function for mitosomes (and mitochondria) across eukaryotes.

Canonical mitochondria still contain a small genome that is a remnant of the genome of the original α -proteobacterial symbiont. This genome usually encodes some ribosomal RNAs and a few (up to ~70) proteins, especially certain components of the electron transport chain. By contrast, both parabasalid hydrogenosomes and *Giardia* mitosomes have completely lost their genomes, and presumably, their translation machinery. Thus, all of the proteins that function in these hydrogenosomes or mitosomes must be encoded by the nuclear genome and imported to the organelle post-translationally.

Fig. 8 Diagram showing the core metabolic pathway of the parabasalid hydrogenosome. Pyruvate is partially oxidized, yielding acetate and carbon dioxide. Electrons are ultimately accepted by protons (rather than by oxygen, as is typical of mitochondria), yielding hydrogen gas. 1 ATP is generated per molecule of pyruvate processed. PFO, pyruvate:ferredoxin oxidoreductase; Hyd., hydrogenase; Fd, ferredoxin; Succ., succinate; Succ.-CoA, succinyl-CoA. Redrawn from several sources, including Hrdy, I., *et al.*, 2008. Metabolism of trichomonad hydrogenosomes. In: Tachezy, J. (Ed.), *Hydrogenosomes and Mitosomes: Mitochondria of Anaerobic Eukaryotes*. Berlin: Springer-Verlag, copyright 2008 Springer-Verlag Berlin Heidelberg, reproduced with kind permission of Springer Science and Business Media.

Convincing mitochondrion-related organelles have never been observed in electron microscopy studies of oxymonads. Recently, -omic-level investigations of oxymonad molecular biology were conducted, including genome sequencing of *Monocercomonoides exilis*. These studies have shown that oxymonads lack the mitochondrial ISC system for iron-sulfur cluster assembly, and instead encode proteins of the SUF system, an iron-cluster assembly machinery found in plastids (chloroplasts), some prokaryotes, and in the cytoplasm of just a couple of other groups of eukaryotes. This SUF machinery was acquired by horizontal gene transfer from a prokaryote, very likely in a common ancestor of Preaxostyla (since *Trimastix* and *Paratrimastix* also have SUF, and seem to lack ISC). However, in addition to lacking the ISC system, no trace of any other signature mitochondrial proteins, for example protein import machinery components and mitochondrial chaperones, could be found in the *Monocercomonoides* genome. It is most likely that *Monocercomonoides*, and perhaps all oxymonads, have completely lost the mitochondrial organelle. If so, oxymonads are the only living eukaryotes known to be completely amitochondriate in the literal sense.

Genetics and Genomics

The genome of *Giardia* is small and compact for a eukaryote. At ~12 Mb in size and with ~5000–6500 protein-coding genes it is similar in size and coding capacity to the genome of brewer's yeast, *Saccharomyces cerevisiae*. The intergenic regions in *Giardia* are short, and adjacent genes sometimes even overlap. A comparable organization was found in the slightly larger genome of the hexamitine diplomonad *Spironucleus salmonicida*. The *Trichomonas vaginalis* genome is much larger (~160 Mb), with at least 25,000 genes interspersed with numerous repetitive elements, and there is evidence of recent and dramatic genome expansion. Interestingly, spliceosomal introns are very sparse in both diplomonads and parabasalids; there are ~65 in *Trichomonas* and just eight identified in *Giardia*, for example. The recently sequenced genome of the oxymonad *Monocercomonoides* is ~75 Mb in size and, unlike the genomes of parabasalids and diplomonads, contains many spliceosomal introns. Metamonad genomes seem to have been shaped significantly by lateral gene transfer. The bulk of the transferred genes are metabolic genes that have been acquired from prokaryotes, probably more than 100 in the case of *Giardia*. Most of these are probably stable long-term transfers, as a large fraction of the genes of foreign origin in diplomonads are shared by *Giardia* and *Spironucleus*.

One issue of interest in diplomonads is whether or not their two nuclei are genetically equivalent. Prior to cell division both nuclei undergo mitosis, and one copy of each of the parent nuclei is passed on to each daughter cell. In other words, each nucleus could, in principle, act as a separate lineage and diverge in sequence from the other over evolutionary time. Nonetheless, most of the evidence to date from *Giardia* suggests that the nuclei are, in fact, equivalent (although karyotypic differences have been recorded too). A process of internuclear genetic transfer has been documented in *Giardia* cysts, providing a possible mechanism for homogenization of the nuclear genomes. If diplomonads are truly sexual (see below) this may also act as a homogenization mechanism.

Various lines of evidence indicate that at least some diplomonads, parabasalids, and/or oxymonads are sexual. Over the 1940–1960s L.R. Cleveland examined and described sexual cycles in several large parabasalids and oxymonads from wood-eating insects. These light-microscopy-based accounts record gamete formation, meiosis, fertilization events, and autogamy (i.e., fusion of gametic nuclei within a single cell). However, these phenomena await reexamination with modern microscopic techniques. Recent attention has focused on small parasitic forms, and molecular approaches. Diplomonads and parabasalids both

have genes that encode proteins required for meiosis, and evidence suggests that there was genetic recombination in the ancestry of various contemporary strains of both *G. intestinalis* and *T. vaginalis*. Interestingly, while the nuclei of *G. intestinalis* appear to be diploid, the strain WB (from which the first genome sequence was derived) is almost completely homozygous. This is not what would be expected from a long history without recombination, over which the homologous chromosomes should diverge from one another in sequence.

Important Pathogenic Species

Diplomonads, parabasalids, and their relatives are mostly harmless commensals or beneficial symbionts found in the digestive tracts of both vertebrates and invertebrates. However, some species are pathogenic and cause various diseases of the intestine, urogenital tract, or other internal organs. The following is a brief discussion of some of the diseases caused by these organisms, especially those affecting humans and domestic animals.

Giardia intestinalis (synonyms: *G. duodenalis*, *G. lamblia*) is a parasite of the small intestine of humans and many animals, and several genetic lineages (assemblages) exist. Two of these lineages, assemblages A and B, are anthroponozoonotic; humans may be infected from a wide variety of both domestic and wild animals. In the developing world there is also extensive person-to-person transmission due to sewage contamination of drinking water, and prevalence is high (~20%–30%). The disease caused by *G. intestinalis*, giardiasis, is also called beaver fever or backpacker's diarrhea. Humans contract giardiasis by ingestion of water or food that contains *Giardia* cysts. Occasionally, transmission may be via fecal–oral or sexual routes.

After the passage of tetranucleate cysts through the stomach the binucleate trophozoites are released. These adhere to enterocytes of the small intestine, thereby blocking nutrient absorption. Following an incubation period of one to a couple of weeks, the main symptom of giardiasis manifests – bloodless and non-festering slimy diarrhea that may be accompanied by stomach ache, nausea, vomiting, and loss of appetite. As lipids are not effectively absorbed by the infected small intestine, the diarrheic feces are often white and oily, and float in water. The disease usually abates spontaneously in a few weeks, but may persist for years without treatment in some cases (although a large proportion of infections are asymptomatic). Giardiasis is treated with 5-nitroimidazole derivatives (metronidazole, tinidazole). *Giardia intestinalis* also causes an intestinal disease in some domestic animals that is similar to human giardiasis. Three nonpathogenic or slightly pathogenic relatives of *Giardia* also live in the human large intestine: *Enteromonas hominis* (an 'enteromonad' species belonging to Hexamitinae), *Chilomastix mesnili*, and *Retortamonas intestinalis* (the latter two are retortamonads).

Spironucleus is a genus of hexamitine diplomonads that includes several species that cause enteritis, skin disease, or systemic infections of fish, birds, and rodents. *S. salmonicida* has caused serious mortality in farmed salmonid fish.

Trichomonas vaginalis causes human urogenital trichomoniasis, perhaps the most prevalent sexually transmitted disease. There are estimated to be more than 170 million infections worldwide. The incubation period lasts from a few days to a few weeks. The infection is asymptomatic or accompanied by only mild symptoms in most men and approximately half of women, and these people serve as carriers of the disease. Rarely, epididymitis and prostatitis, or even sterility, may develop in some men. The infection is typically more severe in women, and can include inflammation of the vagina and womb accompanied by 'strawberry cervix'. In these cases, the normal vaginal microbiota is perturbed and a fetid discharge develops. Although the symptoms usually disappear spontaneously after some time, *Trichomonas* cells persist in the vagina and inflammations may reappear in the future. Acute trichomoniasis during pregnancy may cause premature birth, and in some long-term untreated cases it has caused sterility. Persons with trichomoniasis are also considerably more susceptible to HIV infection due to inflammation of the genital mucosa. Human urogenital trichomoniasis is treated with 5-nitroimidazole derivatives (usually metronidazole or ornidazole), and it is necessary to treat both sexual partners even if the symptoms have developed in only one of them. A closely related species, *T. tenax*, lives in the human oral cavity and is usually considered to be nonpathogenic, although its harmlessness has been disputed by some workers. At least two trichomonad parabasalids live in the human large intestine. Of these, *Pentatrichomonas hominis* is a probably nonpathogenic commensal whereas the aflagellated, ameboid *D. fragilis* may be involved in some intestinal disorders.

Tritrichomonas suis, more commonly known by its synonym *Tritrichomonas foetus*, lives in the nasal cavity of pigs and the urogenital tract of cattle. Although harmless to pigs, *T. suis* is highly pathogenic to cattle and causes bovine urogenital trichomoniasis. The epidemiological role of pigs has not been elucidated yet and transmission between pigs is probably fecal–oral. In cattle, however, *T. suis* is transmitted sexually. In infected bulls, the disease has only mild symptoms and they serve as lifelong carriers of the parasite. In cows, *T. suis* causes serious inflammation of the vagina and womb, and the infected cow may abort and/or become sterile. Bovine urogenital trichomoniasis was effectively treated with metronidazole; however, the application of metronidazole to domestic animals has been prohibited in several countries including the United States and European Union countries. As a result the disease is now virtually untreatable and the infected animals have to be destroyed. Artificial insemination is an effective prevention.

Histomonas meleagridis and *Trichomonas gallinae* are pathogens of poultry. The unflagellated *H. meleagridis* lives in the large intestine of chickens and turkeys and is transmitted between birds by the eggs of the intestinal nematode *Heterakis gallinarum*. *Trichomonas gallinae* occurs in the beak and crop of pigeons and is transmitted by water or by predation (to birds-of-prey). Under some circumstances, these parasites are capable of invading the intestinal mucosa (*H. meleagridis*) or oral mucosa (*T. gallinae*) and may then be transported via the blood to the internal organs. The resulting diseases are then often lethal for the hosts.

Glossary

- Amitochondriate** Lacking mitochondria.
- Anaerobic** In absence of oxygen.
- Bicellular** Consisting of two cells.
- Biflagellated** Carrying two flagellae.
- Binucleate** Containing two nuclei.
- Dictyosomes** Membrane stacks of the Golgi apparatus.
- Dispersal** Spreading over specific distances.
- Dormancy** Resting period.
- Heterotroph** Feeding on other organisms.
- Keratitis** Inflammation of the cornea.
- Macroscopic** Scale large enough to see with naked eye.
- Methanogenic** Producing methane.
- Microaerobic** In presence of small amounts of oxygen.
- Mixotroph** Using a combination of feeding and photosynthesis.
- Monophyletic** Group sharing a single last common ancestor.
- MRSA** Methicillin-resistant *Staphylococcus aureus*.
- Multiciliated** Bearing multiple cilia.
- Multinucleate** Containing several nuclei.
- Phagocytically** Eating by engulfing food particles into membrane-bound vesicles.
- Plasmotomy** Pinching off from the multinucleate cytoplasm without mitosis.
- Proteinaceous** Made from protein.
- Protoplasm** All internal fluids and organelles of a cell.
- Pseudopodium** Temporary cytoplasmic protrusion.
- Sensu strictu** In the strict sense.
- Solitary** In isolation, alone.
- Sorocarp** Fruiting body consisting of a spore mass and stalk.
- Sporocarp** Fruiting body made of one or very few spores on top of a secreted stalk.
- Synapomorphy** Group-defining trait inherited from the last common ancestor.
- Tetranucleated** Containing four nuclei.
- Trophozoite** Feeding stage of a cell.
- Unicellular** Consisting of a single cell.
- Uninucleate** Containing a single nucleus.
- Xenogenous** Of foreign origin.

Introduction

Amoebas are generally known as a unicellular organisms that have no defined shape and are constantly shifting form. From the early beginnings of microscopic studies those shapeshifting cells have captured the interest of observers and for a long time have resisted consistent classification. Amoeboid protists with pseudopodia or locomotive protoplasmic flow have been placed in artificial classes like Rhizopoda (von Siebold, 1848) or Sarcodina (Levine et al., 1980). However, these morphologically similar groups of organisms form very different branches of the eukaryotic tree, which are not necessarily related. With the availability of molecular data those systems had to be abandoned. In this review I will concentrate on Amoebozoa *sensu strictu*, i.e., as a group of related eukaryotic organisms displaying typical amoeboid movement (Fig. 1) that descended from a common ancestor.

The origin of Amoebozoa is estimated to lie about 1.2 billion years ago. Even though some Amoebozoa are large enough to be observed by the naked eye, it was only after the invention of proper functioning microscopes in the 1670s that they sparked the curiosity of many researchers. With his seminal observations of moving ‘animalcules’ in pond samples Antonie van Leeuwenhoek perceived the idea of a world of microbes beyond our eyesight. So much so, that almost every biology class nowadays includes a demonstration of live amoebas. Even though the cells have no fixed shape, moving amoebas possess a more or less dynamically

Fig. 1 Amoeboid movement. The characteristic amoeboid movement involves the formation of dynamic cell protrusions termed pseudopods. This type of movement is common in many Amoebozoa, other amoeboid organisms and even some cells in our body, for instance macrophages and sarcoma cells. Importantly, in Amoebozoa pseudopods are never supported or stiffened by microtubules. The movement is caused by action of an actin-myosin network and different viscosity of the cell cortex (ectoplasm) and inner mass (endoplasm). The ectoplasm is more solid (gel-like) than the fluid endoplasm (sol-like). A pseudopod is formed when the anterior part of the cell becomes more fluid (sol-like) and the hydrostatic pressure exerted by the myosin network at the uroid (arrows) presses the endoplasm forward (II). When migrating in confined spaces this can also cause the formation of membrane blebs where the membrane locally detaches from the cell cortex at the leading edge. The pseudopod then stabilizes due to fresh actin polymerization at the leading edge (III; thick lines), but myosin function, membrane uptake and localized exocytosis also contribute to the process. The pseudopod forms new adhesion sites (III; open arrows) with the substratum and locomotion of the cell occurs due the sol-gel conversion of the cytoplasm within the cell, a process, which is not yet fully understood. Note that established actin fibers (thin lines) don't move with respect to the substratum. Myosin filaments (hatched lines) at the uroid contract and substrate-adhesion sites in the rear are dissolved allowing the cell to move forward (III; open arrows). The movement in many cases can appear random, or non-directed, however often movement is directed with regards to a signal source (chemotaxis, phototaxis, thermotaxis).

stable shape that makes different species recognizable to the trained eye (Fig. 2 panel I). Especially the form of the pseudopods, the shape of the posterior end (uroid), the way the cytoplasm streams and how the cell body as a whole moves are very characteristic and have been used to diagnose species (Fig. 2 panel II). The presence or absence as well as the structure of a cell coat or shell is another diagnostic trait (Fig. 2 panel III). Additionally, when amoebas form dormant cysts, their shape was also used for species diagnosis. Using histochemical staining, amoebas were also differentiated by their specific shape of the nucleolus, and often only a combination of characters gave reliable morphological information to allow species determination. Presently, the 18S small subunit RNA sequence and, where available, the concatenated sequences of many protein coding genes are used to reliably identify and place species.

Individual amoebas can range in size from 3 to 5 μm for the fittingly named *Parvamoeba* ('small amoeba') up to a respectable 5 mm in large specimens of *Pelomyxa palustris*. The multicellular fruiting bodies of some multicellular Dictyostelia can reach over 7 cm length (*Dictyostelium giganteum*), and the syncytial plasmodia of some myxogastrids can cover areas of up to several square meters (Fig. 3(A)) making them the largest unicellular organisms. Several branches of Amoebozoa independently evolved the ability to differentiate encapsulated spores or cysts on a secreted stalk (sporocarp). Others evolved different levels of aggregative multicellularity where many spores are lifted up together in a fruiting body (sorocarp).

Fig. 2 Panel I. Basic amoeba morphotypes (after Smirnov, 2009). (a) polypoidal polytactic (pseudopods can be formed in any direction, sometimes involving subpseudopods); cv – contractile vacuole, fv – food vacuole or other vacuole, gp – granuloplasm with organelles and inclusions, hy – frontal hyaline area, nu – nucleus (with nucleolus), ps – pseudopod, ur – uroid; (b) monopodial orthotactic (single long pseudopod, cell bell-shaped in cross-section with lateral wrinkles); (c) monopodial monotactic (cell tubular in cross-section without wrinkles); (d) spatulate (fan-shaped flattened); (e) striate (flattened cell body with almost parallel dorsal folds); (f) rugose (flattened with irregular dorsal folds and wrinkles); (g) lanceolate (lancet-shaped with distinct lateral flattening); (h) lingulate (flattened, oblong, without any folds); (i) amoeboflagellate (with one or two flagella); (j) floating form (with protruding pseudopods increasing surface area); (k) syncytial (flat, branching, with several or many nuclei); (l) flabellate (flattened with clear anterior hyaline hyaloplasm and uneven frontal edge; no subpseudopodia). Panel II. Basic pseudopod (a–f) and uroid (g–n) shapes. (a) smooth pseudopod; (b) dactylopodia (finger-like protrusions); (c) acanthopodia (stiff spiky pseudopods that are internally supported by microtubules); (d) echinopodia (short spiky pseudopods running in ridges); (e) filopodia (very fine and long pseudopods, not supported by internal microtubules); (f) lobopodia (broad and flat single pseudopod per cell); (g) smooth; (h) morulate; (i) fasciculate; (j) plicate; (k) fingered; (l) villous-bulbous; (m) and (n) trailing cytoplasmic filaments or threads. Panel III. Cell surface coatings. Not to scale.

Diversity

Amoebozoa are unicellular eukaryotes containing the typical set of organelles apart from plastids. They derive from a last common ancestor amoebozoan (LCAA) that had asexual as well as sexual life phases and carried a single flagellum of the eukaryotic $9 \times 2 + 2$ microtubule structure at least at some life cycle stage. The LCAA might also have had some kind of walled resting structure (cyst). Cyst formation, sexual recombination, the flagellum and mitochondria have subsequently been lost in some individual groups. Amoebozoa are situated on the unikont branch of the eukaryotic tree and constitute a sister group to the Obazoa, which comprise Fungi, Metazoa (animals) and a number of other protozoan relatives. Other protists with amoeboid movement are found within Rhizaria and Percolozoa. Amoebozoa have previously been defined by the specific shape of their uroid, their nuclear fine structure and division pattern and histochemical staining patterns. Sequencing of individual genes and whole genomes of Amoebozoa has made it possible to infer phylogenetic relationships from molecular data. As a molecular synapomorphy all Amoebozoa have fused mitochondrial *coxI* and *coxII* genes. Amoebozoa are subdivided into the subphyla Discosea, which have a flattened appearance, move mostly with a single broadly lobed pseudopodium and have branched tubular mitochondrial cristae, and Tevosa, which display more varied pseudopod and mitochondria membrane morphology (Fig. 3(B)). The subphylum Tevosa (Tubulinea + Evosa) comprises the classes Tubulinea, Cutosea, Variosea, Archamoebae and Eumycetozoa. Flagellated stages are known in Variosea, Archamoebae and Eumycetozoa and the presence of a specialized microtubular cone-shaped structure connecting the mostly single basal body of the flagellum to the nucleus called karyomastigont has been used to group those together as Conosa. The subphylum Discosea can be divided into the superclasses Flabellinia and Centramoebia. A number of protosteloid amoebas are now also classed under Discosea, but do not form a monophyletic group.

Fig. 3 (A) Myxogastrid plasmodium of undetermined species covering the whole area of a concrete building foundation pit measuring several square meters. Ludwigsau, Germany, 2008. (B). Phylogenetic relationships between major groups of Amoebozoa. After Kang, S., Tice, A.K., Spiegel, F.W., et al., 2017. Between a pod and a hard test: the deep evolution of amoebae. *Molecular Biology and Evolution* 34 (9), 2258–2270. doi:10.1093/molbev/msx162. This synthesis is based on multi-gene phylogenies and previous groupings into the now polyphyletic Lobosa (indicated in grey) and Conosa is also indicated. The occurrence of cysts, sexual processes, sporocarpic (single cyst/spore on acellular stalk) and sorocarpic (aggregation of several cells) fruiting body formation is indicated next to the groups.

Subphylum Tevosa

Superclass Tubulinea

Tubulinea are characterized by tubular pseudopods lacking subpseudopodia. Tubulinea comprises naked amoebae (*Amoeba*, *Chaos*, *Copromyxa*, *Hartmanella*, *Leptomyxa*, *Gephyramoeba*, *Echinamoeba*, *Vermamoeba*) as well as shell-bearing (testate) amoebae (Arcellinida). *Amoeba proteus* is a frequently observed and large fresh-water amoeba and is often used in classroom-demonstrations.

Fig. 4 Kwang W. Jeon accidentally contaminated a culture of the D strain of *Amoeba proteus* with a lethal bacteria strain ('x-bacteria'; possibly *Legionella*). Whilst most of the infected amoebae died, some survived and became dependent on the x-bacteria (xD strains). Killing the bacteria with antibiotics also caused the xD amoebae to die. This newly established endosymbiosis happened reproducibly within only 200 generations. The endosymbiotic bacteria which number about 42,000 per amoeba cell are not digested by the host amoebae, but held in specialized symbiosomes. The exact mechanism for the development of host dependence remains unknown, but it seems to depend on the presence of two plasmids in the x-bacteria and mutual changes in gene regulation of both partners. Interestingly, xD amoebae also show a nucleocytoplasmic incompatibility with symbiont-free D strains in that xD strain nuclei produce a toxic substance similar to the mate-killer strains of the ciliate *Paramecium* which kills non-symbiont bearing cells.

Also known as 'Jeon's Amoeba' it is a famous example for an endosymbiotic event taking place in the laboratory (Fig. 4). *Amoeba* and *Chaos* species can also contain two morphologically distinct types of mitochondria within the same cell. *Copromyxa protea* is the only species within this group to have evolved aggregative multicellularity. *Copromyxa* amoebas normally feed on bacteria within dung, but when they starve, single cells start to encyst either individually into jigsaw piece-shaped cysts called microcysts or after fusion of two amoebas into round double-walled sphaerocysts. Microcysts can remain solitary, or, depending on local amoeba density, other starving amoebas can attach to founder microcysts, climb on top of them and encyst themselves. This results in small tree-like structures of encysted cells that are then called sorocysts. Upon germination, each sorocyst or microcyst releases one single limax-type uninucleate amoeba. The ecological benefit of this form of encystation, or if this aids species dispersal, remains unclear.

Testate amoebae possess an outer shell (test) with one or two openings, which consists entirely of secreted organic material (proteinaceous; *Arcella*-type) or a mix of secreted organic material and xenogenous material, like diatom shells (frustules), sand particles *etc.*, (agglutinate; *Diffugia*-type). In rarer cases the tests are built of secreted inorganic material (*Quadrullella*). All testate amoebae are free-living and common in fresh-water, soils and mosses and feed using their pseudopods on bacteria, protists, fungi, algae and even small animals. Under unfavorable conditions encystation inside the shell is frequently observed. Sexual recombination is known or suspected in *Copromyxa protea*, *Arcella* and *Trichosphaerium*.

Superclass Cutosea

The Cutosea are a species-poor group and are characterized by a non-adhering cell surface coat containing small scales. The shape and size of those scales are species-specific. There are only three marine species so far representing this group, *Sapocribrum chincoteaguense*, *Squamamoeba japonica* and *Armaparvus langidus*.

Superclass Variosea

Variosea contain species with very diverse shapes, like the marine flagellate *Phalansterium solitarium*, the multiciliated amoeba *Multicilia marina*, and the reticulate shaped *Acramoeba dendroidea*. This is a class containing many sporocarpic species, which produce spores or cysts sitting on a secreted stalk. Those were previously grouped as Eumycetozoa together with the cellular and acellular slime molds (Dictyostelia and Myxogastria), but molecular phylogenies showed that the protosteloid sporocarp originated multiple times in the Amoebozoa. Sporocarps usually only contain a single spore or very few spores (2–8) on top of a thin secreted, hollow stalk of 5–250 µm length. The amoeboid stages of many Variosea are characterized by thin and sometimes branched pseudopods like *Acramoeba*, *Grellamoeba*, *Filamoeba* and *Flamella*. The formation of cysts is frequently observed in Variosea.

Superclass Archamoebae

The Archamoebae contain some species that have adapted to anaerobic and microaerobic environments by secondary loss of mitochondria, Golgi stacks and peroxisomes. They were previously believed to be basal eukaryotes, however are now placed within Tevosa. The superclass Archamoebae contains the anaerobic amitochondriate orders Mastigamoebida (*Mastigamoeba*, *Endolimax*, *Iodamoeba*), Entamoebida (*Entamoeba*,) and Pelobiontida (*Pelomyxa*, *Mastigella*). The marine *Mastigamoeba* have a long forward facing flagella and the nucleus is physically attached to its basal body by microtubule ribbons so that the nucleus can be protracted. The life cycle of *Mastigamoeba* can also display amoebae with simple or branched pseudopods, multinucleate cells and cysts. *Endamoeba* and *Endolimax* are found in the guts of animals. Most are harmless commensals and spread as cysts.

Pelomyxa palustris is one of the largest amoebas usually reaching 500–5000 µm size and feeds phagocytically in anaerobic freshwater sediments. It apparently indiscriminately takes up material of the upper layer of substratum and digests usable constituents and is known to even ingest cotton wool and filter paper. *P. palustris* is multinucleate containing up to several thousand nuclei and lacks mitochondria and typical dictyosomes. Besides organic and inorganic inclusions, like sand grains and diatom shells, and storage bodies the cytoplasm harbors several bacterial endosymbionts, some of which are methanogenic. The life cycle of *P. palustris* is complex involving binucleate cells derived by plasmotomy from larger cells or hatched from cysts and cysts with four nuclei. Until recently, the genus *Pelomyxa* was thought to be monospecific with *P. palustris* as the only member and many other described ‘species’ are actually life stages of the same species. However, a second species, *Pelomyxa corona* has been described, which differs in the morphology of the anterior pseudopod. Multinuclearity evolved several times independently in Amoebozoa: In the Myxogastria, *Pelomyxa*, *Trichosphaerium*, *Schizoplasmodiopsis* and *Tychosporium acutostipes*.

A number of *Entamoeba* species (*E. coli*, *E. hartmanni*, *E. polecki*, *E. dispar*) are harmless commensals residing in the large intestine of humans and, like *Endolimax nana*, are transmitted between hosts by desiccation resistant cysts. Lacking mitochondria, they can only survive outside the body as dormant cysts. The same holds true for the human pathogen *E. histolytica*, the causal agent of amoebiasis, where cysts are transmitted by fecally contaminated hands, food and water. From the tetranucleated cyst of *E. histolytica*, which passages through the stomach unharmed, eight trophozoites emerge in the small intestine, move to the large intestine and multiply there by binary fission. Most *E. histolytica* infections are asymptomatic and trophozoites remain in the intestinal lumen and feed on gut bacteria, but about 10%–20% of the infections develop into invasive amoebiasis which causes around 70,000 deaths per year. In the pathogenic phase, *E. histolytica* trophozoites invade tissues of the gut causing bloody diarrhea and can be distributed over the blood stream and colonize other internal organs. A notable exception entirely lacking encystation is *Entamoeba gingivalis*, another commensal living on bacteria in the human oral cavity, where no cyst stage has ever been found and which is transmitted directly as trophozoites by saliva contact.

Superclass Eumycetozoa

The Eumycetozoa, characterized by spore-bearing fruiting bodies, comprise the orders Dictyostelia and Myxogastria. Both are monophyletic and produce macroscopic fruiting bodies containing a large number of encapsulated spores.

Dictyostelia are soil amoebas often isolated from leaf litter of forest soils, which form multicellular sorocarps by aggregation of numerous ‘myxamoebae’. To date, more than 150 species have been described and Dictyostelia have been isolated globally, from the Arctic to the tropics, but there are no marine species known. The haploid free-living amoebae normally phagocytose bacteria and small yeasts in the soil and divide by binary fission. They occasionally engulf each other whole, but the amoebae of *D. caveatum* have the capacity to ingest amoebae of other dictyostelid species by nibbling off pieces. Upon starvation, amoebae secrete a chemoattractant (cAMP, the di-peptide glorin, folate or other substances) and form an aggregate consisting of fewer than ten to thousands of cells. An intermediate, migratory pseudoplasmodium (‘slug’) can occur in some species that can move for extended time periods responding to heat and light to find the soil surface. In the aggregate, cells differentiate into prespore and prestalk cells giving rise to a stalk consisting of dead cells that lifts a sorocarp containing several thousand encapsulated spores above the substratum. In one genus of Dictyostelia, *Acytostelium*, the cellular stalk has been replaced by a secreted thin cellulose tube and their sorocarps are relatively small. Auxiliary structures holding the spore mass in place (upper and lower cup) and anchoring the stalk to the substratum (basal discs, crampons) may be present in some species. The spores are surrounded by a thick coat of glycoproteins and cellulose and remain dormant until food is available again. Unlike fungal spores, Dictyostelid spores are not hydrophobic and require either running water or motile creatures for dispersal. Since no sexual processes take place during multicellular development of the Dictyostelia, spores are haploid and hatch one haploid myxamoeba each. Many species can also encapsulate solitarily as

microcysts or engage in sexual fusion to form macrocysts, a process during which the zygote attracts a number of other myxamoebae before surrounding itself with a thick wall and ingesting them. Specific environmental conditions trigger the pathways for either sorocarp, microcyst or macrocyst formation. Sorocarp formation is favored by relatively dry and light conditions. For microcyst formation wet and dark conditions, combined with solute stress are favorable. Macrocyst formation requires the presence of compatible mating types and high cell density in wet and dark conditions. After a period of dormancy, the macrocyst undergoes one meiotic and several mitotic divisions causing several haploid myxamoebae to hatch from the macrocyst. Rare self-fertile homothallic strains are also known.

The Myxogastria are the most diverse group of Amoebozoa and divide into two clades containing either dark spores containing melanin (Collumellidia: Physarales and Stemonitales) or brightly colored spores containing various organic pigments and only little melanin (Lucisporidia: Liceales and Trichiales). The Echinosteliales with hyaline spores comprise a fifth, more basal order with some affinity to the dark-spored group. In Myxogastrids, a diploid plasmodium forms from the zygote through repeated nuclear divisions without cell division. The plasmodium is often brightly colored and can reach macroscopic dimensions (Fig. 2(A)). Nuclear divisions in the plasmodium are synchronous and often a rhythmic cytoplasmic shuttle streaming in the cytoplasmic strands is observed. This is based on actin-myosin contractions and aids the intracellular nutrient transport and communication within the large plasmodium. The streaming is also responsible for the high speed of movement of the plasmodium of up to 500 mm h⁻¹. External factors, like change in humidity, pH, temperature or starvation can trigger the formation of sporocarps. In some species with colored plasmodia, light is necessary for sporocarp formation and a phytochrome-like light receptor has been described from the genome of *Physarum polycephalum*. Spores give rise to haploid amoebae which may transform into biflagellated amoeboflagellates under wet conditions. If partners of compatible mating types (of which there are 13 or more in *P. polycephalum*) are present, two amoebae or amoeboflagellates can fuse to give rise to a zygote and start a new plasmodium. The macroscopic fruiting bodies of Myxogastria are often found on decaying wood and myxogastrids can also produce cysts confusingly also called macrocysts. *Ceratiomyxa* has recently been established as a sister group to Myxogastria and its large hyaline plasmodium is probably homologous to the plasmodia of myxogastrids, even though its mode of external spore production resembling protosteloid sporocarps is different from the sporulation within an enclosed structure (peridium) of Myxogastria. *Physarum polycephalum* is one of the best-studied myxogastrids and because it is easy to grow in the laboratory it has yielded important and surprising insights into amoeboid movement and cell motility. It even has been shown to possess a primitive “intelligence” being able to solve mazes, learning to anticipate events and finding the most efficient network connecting oat flakes representing Japanese towns with Tokyo.

Subphylum Discosea

Flabellinia

Flabellinia contain some strongly flattened amoebas with amorphous glycocalyx, like *Vannella* and *Mayorella*, but their life cycles as well as within-group relationships are mostly unknown. *Vannella* typically have fan-shaped frontal pseudopodia, but there are also species with finger-like pseudopodia (*Vexillifera*). Lingulate (tongue-shaped) and lanceolate (lancet-shaped) forms and species with rigid dorsal surface ridges (*Stenamoeba*, *Thecamoeba*) or a thick cuticle (*Dermamoeba*) also occur. Some *Vannella* species harbor intracellular bacteria that are pathogenic to humans. Cysts have been reported to be formed by *V. cutleri* and *V. peristens*. *Neoparamoeba* spp., free-living marine amoebas with unknown life cycle and opportunistic parasites, are the cause of amebic gill disease in salmon and other farmed fish. *Sappinia diploidea* forms large binucleate trophozoites and bicellular cysts, which can fuse to a single cell and probably represent a sexual stage. *Sappinia pedata* forms a ‘standing amoeba’, the reason why it was sometimes included in the protostelids, however, no spore formation takes place, the stalk remains an integral part of the cell and the process is reversible. Aggregation of cells has been reported in *S. pedata*, but no sorocarp formation has ever been observed.

Centramoebia

The genus *Parvamoeba* is the smallest amoeba known and consists of only two known species (*P. rugata* and *P. monoura*) that are at 3–5 µm diameter almost too small to observe by light microscopy. Whereas most Centramoebia are present as solitary amoebae, *Endostelium* spp., *Luapelamoeba hula*, *Luapelamoeba arachisporum* and *Acanthamoeba pyriformis* form minute sporocarpic fruiting bodies of the protosteloid type.

The *Acanthamoeba* life cycle consists of feeding trophozoites carrying spike-like pseudopodia (acanthopodia), which upon starvation transform into double-walled dormant cysts. No sexual stages are known in *Acanthamoeba*, however, a number of sex-genes have been identified in the genome of *A. castellanii*. *Acanthamoeba* spp. have been isolated from many environments including freshwater, seawater, soil, sediments, salt water lakes, Antarctica ice and even from air samples indicating their ubiquitous distribution. They have also been found in many man-made environments like bottled mineral water, factory water discharges, air-conditioning units, sewage, hot water systems and contact lens solutions. The latter two are important, because *Acanthamoeba* can form a reservoir for pathogenic bacteria (MRSA, *Legionella*) and are also themselves opportunistic human pathogen. *Acanthamoeba*-keratitis is most commonly found in contact-lens wearers, who do not observe strict contact-lens hygiene, but can also affect other people. Here, *Acanthamoeba* is introduced into the eye as trophozoites that first feed on the bacterial biofilm on the contact lenses and later can enter the cornea through pre-existing micro-injuries and start to ingest

corneal cells leading to painful infection and sometimes even blindness. The extremely rare, but more severe condition granulomatous amebic encephalitis (GAE) is caused by *A.castellani*, *A.culbertsoni*, *A.polyphaga*, *Hartmanella* and *Balamuthia mandrillaris*. GAE occurs mostly in immunocompromised individuals, but is almost always fatal. Here, *Acanthamoeba* enters the blood-stream over cuts in the skin or the oral-nasal route and may colonize other inner organs (lungs, liver, and kidneys) first. Those infections can be asymptomatic until the trophozoites cross the blood-brain barrier and infect the brain causing lethal neurological damage and typical granulomas.

Ecology and Distribution

Amoebozoa are typically heterotrophs with the exception of some mixotrophic species of testate amoebae (*Amphitrema flavum*, *Diffugia oblonga*, *Hyalosphenia papilio*) which harbor numerous photosynthetic *Chlorella* endosymbionts in their cytoplasm. Most are free-living in soil, freshwater, on plants, in brackish or sea water and, considering the large number of over 1500 described species, only a small number of these are parasites of humans and other animals. Amoebozoa live in aerobic or anaerobic habitats and the loss of mitochondria of parasitic or anaerobic species is a secondary adaptation to those environments. Amoebozoa play an important role as primary grazers on bacteria in soil and freshwater and are important for nutrient cycling as they are the prey of larger animals, like nematodes. Most Amoebozoa divide clonally by binary division and sexual processes are rarely observed, within most individual species and within the whole group. Life cycles of many Amoebozoans involve durable cyst stages, which can be a means of species dispersal and be deposited as seed banks to repopulate the habitat after periods of dormancy. Some cysts have even been recovered from 8,580-year old permafrost soil samples and hatched viable actively dividing amoebas. The cysts of some species can be airborne and distributed with wind currents over vast distances.

Defining Statement

The catalytic properties of α -amylase, β -amylase, glucoamylase, debranching enzymes, CGTase, pullulanases and pullulan hydrolases, and other enzymes are described to clarify the differences among them and their microbial sources. The structures of Taka-amylase, CGTase, β -amylase, glucoamylase and pullulanase are explained with a focus on their domain structures, catalytic site structures and identification, and position of two catalytic residues.

Definition of Amylase

In this article, amylases are defined as a group of enzymes that act on α -1,4- and α -1,6-glucosidic bonds present in starch and glycogen, a starch-related polysaccharide. Amylases, in most simple terms, are a group of glycosyl hydrolases, which hydrolyze α -1,4- and/or α -1,6-glucosidic bonds of starch and glycogen. The structural information on the enzymes has expanded the concept of amylase and classified the enzymes in GH-13 family. It is sometimes difficult to discriminate certain enzymes from amylase, depending on their action specificity. Here, enzymes that act only on oligosaccharides derived from starch were excluded from amylase. Although some phosphorylases act on starch or glycogen, they are not included in amylases.

Substrate of Amylases

The Substrate Starch

Starch is the storable form of energy produced by all green plants and is utilized by almost all living organisms on this planet as their energy source. Plants store starch in the form of semi-crystalline granules in fruits, seeds, rhizomes and tubers. The diameter of the granules is in the range of 1–100 μ m and the characteristics of the starch depend mainly on the location in the plant where the starch is present. High starch content is found in potatoes, maize, wheat, rye, sorghum, rice, barley, peas and tapioca. Starch, also called amylum, is a polysaccharide of glucose/ α -D-glucopyranose in the 4C_1 conformation. Starch is stored in the plants as granules composed of amylose and amylopectin. Amylose is a water insoluble polyglucan which constitutes about 20%–27% of starch and is essentially linear with 100–10,000 α -D-1,4-linked anhydrous glucose units but with a few ($\sim$ 10) branch points per molecule. Amylopectin with a much larger molecule (DP 104–105) constitutes the bulk of starch consisting of α -D-1,4-linked glucose units and joined by α (1 $\rightarrow$ 6) linkages (Fig. 1(a–b)) after every 24–30 glucose units. Regular branching in amylopectin molecule allows the formation of crystalline structure. Amylopectin accounts for 75%–85% of normal starch. Starch molecules are specific in structure and composition (the length of glucose chains or the amylose/amylopectin ratio), as well as the protein content of the storage organs. Starch has, therefore, various industrial uses depending on the agricultural raw material from which it is extracted. Waxy starch found in some waxy plants such as waxy corn or waxy rice is composed solely of amylopectin. In nature, starch is present as insoluble starch granules (raw starch), which have a crystalline structure. Most of the research on amylases, whether basic or application oriented, has been conducted on gelatinized starch, which is a starch solution obtained by heating starch granules in water.

[☆]*Change History:* 2017. Nisha Mohanan and Tulasi Satyanarayana introduced small edits in the abstract, defining statement and classification of amylases; added the sections: 'Pullulan hydrolases' and 'References', subsections, 'Pullulan', 'Starch liquefaction and saccharification', 'Antistaling agent in making of bread and other baked products', 'Detergent application', 'Preparation of cyclodextrins', 'Preparation of resistant starch' and 'Preparation of panose and isopanose containing syrups'; and updated the sections: 'Definition of Amylase', 'Substrate of Amylases', 'Glucoamylase', 'Debranching enzymes', 'Neopullulanase', 'CGTase', 'Glucoamylase', 'Engineering of Amylases' and 'Industrial applications of Amylases'.

This article is an update of H. Taniguchi, Y. Honnda, Amylases, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 159–173.

Fig. 1 Schematic representation of amylopectin, glycogen, and pullulan. (a) Horizontal lines represent α -1,4-linked glucan chains and arrow heads represent α -1,6 linkage at the branch points. (b) Enlarged structure around the branching point where hexagon with a small ring stands for glucose residue. (c) Open circles stand for glucose residues linking through α -1,4 linkage and closed circles stand for glucose residues linking through α -1,6 linkage at the branch points. (d) Same symbols as in (b).

Glycogen is a storage α -glucan found in animals and microorganisms. Like amylopectin, it consists of α -1,4-linked glucans connected via the α -1,6 linkage (branching). This branching occurs frequently and is distributed evenly throughout the glycogen molecule as shown in Fig. 1(c), and makes glycogen soluble in water. Amylase acts on both of these α -polyglucans.

The Substrate Pullulan

Pullulan is an extracellular glucan synthesized by the fungus *Aureobasidium pullulans*, formerly known as *Pullularia pullulans*. It is composed of linearly polymerized maltotriose units linked by α -1, 6-glucosidic bonds (Fig. 1(d)), although the same can occur as a

polymer of isopanose. It is a highly ordered and branched polysaccharide with 2:1 ratio of α -1, 4-glycosidic to α -1, 6-glycosidic bonds. The α -1, 6 linkages in pullulan are considered to mimic partially the α -1, 6-branch points of amylopectin. Pullulan plays an important role as a model substrate for assaying starch-debranching enzymes. Pullulan is soluble in water and forms a colorless and viscous adhesive solution but insoluble in solvents such as ethanol, methanol and acetone. Pullulan has potential applications in food, pharmaceutical, and biomedical industries and is often used to determine the substrate specificities of amylases.

Classification of Amylases

Amylases are classified based on the catalytic properties of enzymes, such as substrate and product specificities. Microbial amylases with their EC numbers (IUBMB Enzyme Nomenclature) are shown in Table 1. These enzymes fall into three EC classes: transferases (EC 2), hydrolases (EC 3), and isomerases (EC 5), and most of these enzymes belong to the EC 3 class. The enzymes can be divided into two groups, retaining and inverting based on their action mechanism. The anomeric configuration in the substrate is retained after the catalytic action in retaining enzymes, whereas it is inverted after the catalytic action in inverting enzymes. β -Amylase (EC 3.2.1.2) and glucoamylase (EC 3.2.1.3) are inverting enzymes, whereas all other enzymes including α -amylase (EC 3.2.1.1) are retaining enzymes.

Microbial amylases are further classified on the basis of their action specificity towards α -glucan chains. These are classified as either exo-acting or endo-acting. β -Amylase and glucoamylase are exo-acting enzymes as they release maltose or glucose, successively from the non-reducing end of α -glucans. In contrast, α -amylase is an endo-acting enzyme because it cleaves the inner glycosidic bonds of α -glucans to produce oligosaccharides with various DPs.

Based on the vast amount of information on primary and tertiary structures of enzymes, Henrissat proposed a new classification method for carbohydrate-active enzymes. Currently, all glycoside hydrolases (GHs) are classified into 110 GH families (CAZy database at See Relevant Websites section, October 2007), and all microbial amylases are classified into 5 GH families: GH 13, 14, 15, 31, and 77. As shown in Table 1, enzymes with various catalytic specificities, therefore, various EC numbers, belong to the GH 13 family. The enzymes belonging to the GH 13 family possess seven conserved amino acid sequences and a $(\beta/\alpha)_8$ barrel structure. Recently the GH 13 family was further subdivided into 35 subfamilies based on detailed structural differences. This makes it possible to approximately correlate enzymes with specific EC numbers to those with specific GH families or subfamilies as summarized in Table 1.

Catalytic Properties of Amylases

α -Amylase (EC 3.2.1.1, GH 13-1, 2, 5, 6, 7, 15, 19, 20)

This enzyme plays a central role in the hydrolysis of starch, both in nature and in the starch industry. It is found in a wide range of living organisms because starch is the most important energy source for known living organisms. Large amounts of data on enzymes

Table 1 Enzymes belonging to amylase

Enzyme name	EC number	GH family	GH 13 subfamily	Mechanism	Mode	Fold	Base	Acid
α -Amylase	3.2.1.1	13	1, (2), 5, 7, (19), 27, 28, 32	Retaining	Endo	$(\beta/\alpha)_8$	Asp	Glu
β -Amylase	3.2.1.2	14		Inversion	Exo	$(\beta/\alpha)_8$	Glu	Glu
Glucoamylase	3.2.1.3	15		Inversion	Exo	$(\alpha/\alpha)_6$	Glu	Glu
Oligo-1,6-glucosidase	3.2.1.10	13	31	Retaining	Endo	$(\beta/\alpha)_8$	Asp	Glu
α -Glucosidase	3.2.1.20	13	21, 29	Retaining	Exo	$(\beta/\alpha)_8$	Asp	Glu
		31					Asp	Asp
Amylo-1,6-glucosidase	3.2.1.33	13	25	Retaining	Exo?	$(\beta/\alpha)_8$	Asp	Glu
Pullulanase	3.2.1.41	13	12, 13, 14	Retaining	Endo	$(\beta/\alpha)_8$	Asp	Glu
Cyclomaltodextrinase	3.2.1.54	13	(20)	Retaining	Endo	$(\beta/\alpha)_8$	Asp	Glu
Glucan-1,4- α -maltotetrahydrolase	3.2.1.60	13	NC	Retaining	Exo?	$(\beta/\alpha)_8$	Asp	Glu
Isoamylase	3.2.1.68	13	11	Retaining	Endo	$(\beta/\alpha)_8$	Asp	Glu
Glucan-1,4- α -maltohexaohydrolase	3.2.1.98	13	(19)	Retaining	Exo?	$(\beta/\alpha)_8$	Asp	Glu

Glucan-1,4- α -maltotriohydrolase	3.2.1.133	13	(20)	Retaining	Endo	$(\beta/\alpha)_8$	Asp	Glu
Neopullulanase	3.2.1.135	13	(20)	Retaining	Endo	$(\beta/\alpha)_8$	Asp	Glu
4- α -D-glucanotrehalose trehalohydrolase	3.2.1.141	13	10	Retaining	Exo?	$(\beta/\alpha)_8$	Asp	Glu
Branching enzyme	2.4.1.18	13	9	Retaining	Endo	$(\beta/\alpha)_8$	Asp	Glu
Cyclomaltodextrin glucanotransferase	2.4.1.19	13	2	Retaining	Endo	$(\beta/\alpha)_8$	Asp	Glu
4- α -Glucanotransferase	2.4.1.25	77		Retaining	Endo	$(\beta/\alpha)_8$	Asp	Glu
4- α -Glucan 1- α -D-glucosylmutase	5.4.99.15	13	26	Retaining	Exo?	$(\beta/\alpha)_8$	Asp	Glu

Note: NC, not classified; NK, not known.

of this group from animals, plants, and microorganisms have been accumulated. As a microbial amylase, the enzyme from *Aspergillus oryzae* has been studied most extensively, and the information on this enzyme constitutes the majority of our knowledge on α -amylase as described in the following section.

α -Amylase hydrolyzes the α -1,4 linkages in α -glucan but cannot hydrolyze the α -1,6 linkages. In the early stage of hydrolysis, dextrans with relatively higher molecular weights are produced, with a rapid decrease in the viscosity of starch solution. As the hydrolysis proceeds, the average DP of dextrans decreases gradually, and in the final stage of hydrolysis, large amounts of maltose, maltotriose, glucose, and oligosaccharides (α -limit dextrans) with the α -1,6 linkage constitute the hydrolysis products. All hydrolysis products have an α -configuration. Profiles of product composition during hydrolysis differ greatly depending on the origin of the enzyme. Some show a sharp decrease in viscosity in the early stage of hydrolysis, whereas others show a relatively slow decrease in the same stage. Enzymes of this group have been purified and characterized from a wide range of microorganisms, including archaea such as *Sulfolobus*, prokaryotes such as *Bacillus*, and eukaryotes such as *Aspergillus*. Most of them have maximum activity at 30–37°C at a neutral pH; however, some exhibit maximum activity at pH values as low as 3 or as high as 10 and at temperatures more than 100°C. Enzymes from *Aspergillus niger*, *A. oryzae*, *Bacillus amyloliquefaciens*, *B. circulans*, *B. licheniformis*, *B. stearothermophilus* and *B. subtilis* are of special importance from the standpoint of both basic research and industrial application. All enzymes of this group are classified into the GH 13 family, and their structure contains a $(\beta/\alpha)_8$ barrel with Glu as a proton donor and Asp as a nucleophile on its catalytic sites. They are further classified into eight subfamilies, as shown in Table 1.

β -Amylase (EC 3.2.1.2, GH 14)

Enzymes of this group were discovered long after α -amylase had been believed to be present only in the plant kingdom. In 1974, *Bacillus megaterium* was found to produce β -amylase for the first time in the microbial kingdom. Since then, several microorganisms such as *Bacillus*, *Pseudomonas*, and *Streptomyces* have been reported to produce these enzymes. Enzyme proteins were purified from several strains, and their catalytic and structural properties were studied and compared with those of plant β -amylase. There is no major difference in the properties of plant and microbial enzymes, and both enzymes are classified into the EC 3.2.1.2 and GH 14 groups. β -Amylase hydrolyzes the α -1,4 linkage next to the non-reducing end of α -glucan, which successively yields maltose in a β -configuration as the sole low-molecular-weight product. It cannot hydrolyze the α -1,6 linkages. When amylopectin is subjected to the action of this enzyme, α -1,4glucan chains in the highly branched molecule are trimmed down from the chain end towards the α -1,6 branching points. This action completely stops at four glucose units before the branching points, which produces β -maltose and the high-molecular-weight branched dextrin (β -limit dextrin). Thus, β -amylase contrasts sharply with α -amylase in terms of its action mechanism (inverting versus retaining) and action specificity (exo-acting versus endo-acting). Structurally, it has the same $(\beta/\alpha)_8$ barrel as α -amylase; however, two Glu residues act as a proton donor and a nucleophile.

Glucoamylase (EC 3.2.1.3, GH 15)

Intensive investigations of fungal amylase by Japanese researchers in the 1950s yielded a new type of amylase. This new amylase produced β -glucose from starch as the sole reaction product and was named glucoamylase. As it was the third amylase discovered following α - and β -amylases, it was once called γ -amylase or amyloglucosidase. It catalyzes the hydrolysis of successive α -1,4 linkages in the non-reducing ends of glucans, thereby producing β -D-glucose as the sole hydrolysis product. Thus, glucoamylase is an inverting type and exo-acting enzyme, similar to β -amylase. It also hydrolyzes the α -1,6 linkage, although at a rate lower than that of the α -1,4 linkage hydrolysis. This is a remarkable feature of glucoamylase compared with α - and β -amylases and makes it the only enzyme that can hydrolyze starch completely into glucose. In industrial starch saccharification, glucoamylase plays an important role together with α -amylase. At high starch (and therefore, glucose) concentrations (e.g., 40%), this enzyme catalyzes a condensation reaction to yield maltose and isomaltose. This reaction prevents 100% yield of glucose in industrial starch saccharification. Glucoamylase is produced mainly by fungi such as *A. oryzae*, *A. niger*, *Rhizopus delemar*, *Rhizopus oryzae* and *Rhizopus niveus*. Bacteria seldom produce this type of enzymes. Enzymes from *Aspergillus* and *Rhizopus* are widely produced by enzyme manufacturers. Glucoamylase has an $(\alpha/\alpha)_6$ structure, different from the $(\beta/\alpha)_8$ structure of α - and β -amylases. Both the proton donor and the nucleophile in the catalytic sites of this enzyme are Glu residues.

Most of the fungi and some yeast produce more than one form of enzyme, and these forms may have different molecular mass, amino acid composition, glycosylation, ability to digest raw starch and stability (Jensen and Olsen, 1999). The two forms of glucoamylases have been reported from the commercially used *A. awamori* and *A. niger* (Takahashi et al., 1981; Svensson et al., 1982; Yasuda et al., 1989; Hatada et al., 1997), a type-I strain of *R. oryzae* NRRL 395 (Mertens and Skory, 2007). While *Rhizopus* sp., *R. delemar*, *A. oryzae*, *A. niger* Bo-1 and *Arthrobotrys amerospora* ATCC 34468 produce three different forms of the enzyme (Takahashi et al., 1978; Mitsue et al., 1979; Abe et al., 1985; Norouzi et al., 2000) and the five and six different forms of glucoamylases have been reported from *Corticium rolfsii* AHU 9627 and *Chalara paradoxa*, respectively (Monma et al., 1989). The starch metabolising yeast, *S. cerevisiae* var. *diastaticus* and *Saccharomycopsis fibuligera* produce three and two different glucoamylase forms, respectively (Pretorius et al., 1991; Hostinova, 2002). An amylolytic yeast, *Pichia subpelliculosa* ABWF-64 (Kumar and Satyanarayana, 2001) and thermophilic mould, *Thermomucor indicae-seudaticae* (Kumar et al., 2007) are known to produce

glucoamylases. Glucoamylases have also been reported from the thermoacidophilic Archaea, *Thermoplasma acidophilum*, *Picrophilus torridus* and *Picrophilus oshimae* (Serour and Antranikian, 2002) and the hyperthermophilic archaeon, *Sulfolobus solfataricus* (Kim et al., 2004).

Debranching Enzymes

Five enzymes can be grouped in this category: oligo-1,6-glucosidase (EC 3.2.1.10), amylo-1,6-glucosidase (EC 3.2.1.33), isoamylase (EC 3.2.1.68), pullulanases (type I and II, EC 3.2.1.41 and EC 3.2.1.1/41) and pullulan hydrolase type III. All these enzymes, except amylopullulanases and pullulan hydrolases type III, hydrolyze only the α -1,6 linkage in starch, glycogen, and the oligosaccharides derived from them to produce sugars with an α -configuration. They cannot hydrolyze the α -1,4 linkage.

Oligo-1,6-glucosidase is present mainly in the animal kingdom (often called isomaltase), although some bacterial species, such as *Bacillus*, can also produce this enzyme. It acts on oligosaccharides with an α -1,6 linkage to produce α -glucose as the main product. Amylo-1,6-glucosidase is usually present as a part of a bifunctional enzyme. This single protein has another catalytic center with 4- α -glucanotransferase (EC 2.4.1.25) activity. When starch or glycogen are digested by phosphorylase (EC 2.4.1.1), glucan chains in these polysaccharides are trimmed down from their nonreducing ends, and phosphorylase-limit dextrans with maltotetraose stubs attaching to other chains through α -1,6 linkages are produced. 4- α -Glucanotransferase (EC 2.4.1.25) activity of the bifunctional protein transfers the maltotriose unit to the non-reducing ends of other chains to form α -1,4 linkage, and its amylo-1,6-glucosidase activity hydrolyzes the remaining α -1,6 glucosyl stubs to release α -glucose. This protein is usually found in animal muscles together with phosphorylase. In the microbial kingdom, *Saccharomyces cerevisiae* is known to contain this enzyme.

In the hydrolysis of starch, pullulanase type I and isoamylase play important roles in both living cells and in the starch industry because they are the only enzymes that selectively hydrolyze α -1,6 linkages in glucans. Both enzymes are endo-acting and produce α -1,4-glucan chains or maltooligosaccharides. Pullulanase type I hydrolyzes pullulan and amylopectin completely or nearly completely; however, it can hydrolyze glycogen only to a limited extent. On the other hand, isoamylase hydrolyzes amylopectin and glycogen completely; however, it cannot act on pullulan. Isoamylase is being used as a powerful tool in the analysis of the fine structure of amylopectin, whereas pullulanase, in combination with β -amylase, is widely used in the starch saccharification industry to produce maltose. Enzymatic properties of isoamylase from *Pseudomonas amyloclavata* have been extensively studied, and an enzyme preparation from *Pseudomonas* sp. is commercially available. Pullulanase preparations from *Klebsiella* sp., *Bacillus brevis*, *B. licheniformis* and *B. acidopulluliticus* are available from several enzyme manufacturers. The enzyme preparation from *B. acidopulluliticus* is thermostable and thus widely used in the starch industry.

The pullulanase type II (amylopullulanases and/or α -amylase-pullulanase) is capable of hydrolyzing both α -1, 4- and α -1, 6-linkages in starch, pullulan, limit dextrans and other polysaccharides. The action of the enzyme on the α -1, 4-linkages of amylose forms DP2-4 products, while pullulan is generally cleaved at α -1,6-linkages to form maltotriose (Nisha and Satyanarayana, 2013b). The amylopullulanases from *Geobacillus thermoleovorans* NP33 (Nisha and Satyanarayana, 2014), *Lactobacillus amylophilus* GV6 (Vishnu et al., 2006) and *Geobacillus stearothermophilus* L14 (Zareian et al., 2010), however, hydrolyze α -1, 4-linkages in maltotriose (pullulan hydrolysate) to release glucose. Because of its action on multiple substrates, the enzyme action results in the complete hydrolysis of polysaccharides to simple sugars without requiring other amylolytic enzymes like α -amylase and β -amylase (Antranikian, 1992; Nisha and Satyanarayana, 2013c). The enzyme is termed as amylopullulanase (Saha et al., 1989) or α -amylase-pullulanase (Kim and Kim, 1995) based on the presence of a single catalytic domain or dual active sites in separate catalytic domains for cleaving α -1, 4- and α -1, 6-linkages. The pullulanase type II from thermophilic anaerobes possess single active site (Mathupala et al., 1993; Ramesh et al., 1994), while that of the aerobic microbes contain either one (Lee et al., 1994; Brunswick et al., 1999) or two active sites for hydrolyzing α -1, 4- and α -1, 6-linkages (Hatada et al., 1997; O'Connell Motherway et al., 2008). While pullulan hydrolase type III cleaves both α -1, 4- and α -1, 6-glycosidic linkages of pullulan to form panose, maltotriose, maltose and glucose. The enzyme also hydrolyzes related polysaccharides like starch, amylopectin, amylose, glycogen and cyclodextrins, and forms maltose as the major product.

All the debranching enzymes have a $(\beta/\alpha)_8$ barrel forming the catalytic domain and are classified into the GH 13 family. The debranching enzymes, excluding pullulanases, are classified into three different subfamilies as shown in Table 1.

Enzymes That Form Maltooligosaccharides With Specific DPs

Glucan-1,4- α -maltotetraohydrolase (EC 3.2.1.60), glucan-4- α -maltohexaohydrolase (EC 3.2.1.98), glucan-1,4- α -maltotriohydrolase (EC 3.2.1.116), and glucan-1,4- α -maltohydrolase (EC 3.2.1.133) produce maltotetraose, maltohexaose, maltotriose, and maltose, respectively, as sole low-molecular-weight products from starch. All these maltooligosaccharides are formed in the α -configuration. All four enzymes are classified in the GH 13 family, and into four specific subfamilies as shown in Table 1. Although glucan-1,4- α -maltopentaohydrolase is not shown in Table 1 and no EC number has been assigned to it, it is found in several microorganisms and is classified in the GH subfamily 13-19 based on its amino acid sequence. This enzyme produces α -maltopentaose from starch. Although all of these enzymes appear to be exo-acting, a detailed study of these enzymes revealed that most of them are actually endo-acting.

These enzymes are produced by a limited number of bacteria. For example, glucan-1,4- α -maltotetraohydrolase is produced by *Pseudomonas stutzeri* and *B. circulans*, glucan-1,4- α -maltohexaohydrolase by *Klebsiella pneumoniae* and *Bacillus* sp.,

glucan-1,4- α -maltotriohydrolase by *Streptomyces griseus* and *Microbacterium imperiale*, glucan-1,4- α -maltohydrolase by *B. stearothermophilus*, *Thermus* sp., and *Streptomyces hygroscopicus*, and glucan-1,4- α -maltopentaohydrolase by *B. licheniformis* and *Pseudomonas* sp. These enzymes are used in the commercial production of maltotriose, maltotetraose, maltopentaose, and maltohexaose produced for food applications in Japan. Glucan-1,4- α -maltohydrolase is often called maltogenic α -amylase, and the enzyme from *B. stearothermophilus* is widely used in baking. The maltogenic α -amylase from *Thermus* sp. has unique characteristics, that is, this enzyme hydrolyzes the α -1,6 and α -1,4 linkages and transfers cleaved oligosaccharides to C3-, C4-, or C6-hydroxyl groups of acceptor sugars.

α -Glucosidase (EC 3.2.1.20, GH 13-21, GH 13-30, GH 31)

Enzymes belonging to this group hydrolyze non-reducing end glucosidic linkage to release α -glucose, in contrast to glucoamylase, which releases β -glucose. These enzymes are found in the animal, plant, and microbial kingdoms. The microbial enzymes from *A. niger*, *Bacillus*, *Penicillium*, *S. cerevisiae*, and *Thermotoga maritima* are studied extensively. They have long been considered to act on low-molecular-weight substrates such as oligosaccharides and glycosides. Recent studies have shown that some of these enzymes act on starch as well. These enzymes hydrolyze not only the α -1,4 linkage but also the α -1,6-, α -1,2-, and α -1,3-glucosidic linkages. A remarkable feature of α -glucosidase is that it has strong transglycosylation activity at higher maltose concentrations. Isomaltooligosaccharides are produced as a food ingredient via the activity of *A. niger* α -glucosidase. Based on amino acid sequences, enzymes of this group are classified in the GH 13 and GH 31 families, the former being further classified into the GH 13-21 and GH 13-30 subfamilies. The GH 31 family also has a $(\beta/\alpha)_8$ barrel; however, it is different from that of GH 13. Both the proton donor and the nucleophile in the catalytic sites of these enzymes are Asp residues.

Cyclomaltodextringlucanotransferase (Cgtase, EC 2.4.1.19, GH 13-2)

Cyclodextrins (CDs) are mixtures of cyclomaltohexaose (α -CD), cyclomaltoheptaose (β -CD), and cyclomaltooctaose (γ -CD). They form inclusion complexes with guest compounds and are used as food ingredients in Japan. Enzymes belonging to CGTase are produced by several species of *Bacillus* such as *Bacillus macerans* and *B. megaterium*. They act on α -glucans such as starch and glycogen to produce a mixture of CDs; the composition varies depending on enzyme sources and reaction conditions. The enzyme from *B. macerans* has been studied extensively. CGTase catalyzes three kinds of transglycosylation reactions: intramolecular transglycosylation, intermolecular transglycosylation, and disproportionation reactions. In the intramolecular reaction (cyclization reaction), the enzymes cleave the α -1,4 linkage of glucans at a certain distance (6, 7, or 8 glucose units) from their non-reducing ends and transfer the newly formed reducing end glucose unit to the C-4 hydroxyl group of the non-reducing end glucose unit of the same glucan chain. CDs are produced by this reaction. In the presence of glucose together with starch or CDs, the enzymes catalyze intermolecular transglycosylation (coupling reaction) to form a series of maltooligosaccharides. Glucose can be replaced with other sugars or glycosides. This reaction of CGTase is also often used in the food industry to add glucose units to other sugars or glycosides for the synthesis of new sugars or for the modification of glycosides. When incubated with maltooligosaccharides of certain DPs, the enzymes disproportionate them to produce a series of maltooligosaccharides. Enzymes of this group cleave the α -1,4 linkages exclusively and form α -1,4 linkages exclusively in their reactions. These enzymes show a hydrolytic reaction, although with low activity, with starch and CDs.

Cyclomaltodextrinase (EC 3.2.1.54, GH 13-20)

Enzymes of this group act preferentially on CDs compared to starch and produce linear maltooligosaccharides. They also hydrolyze linear maltodextrin. Some enzymes of α -amylase (EC 3.2.1.1) can also hydrolyze CDs. The only difference between cyclomaltodextrinase and α -amylase is the high affinities of the former to CDs. Enzymes of this group are produced by several species of *Bacillus* and some other bacteria. They are classified in the same subfamily (GH 13-20) as maltogenic α -amylase (EC 3.2.1.133) and neopullulanase (EC 3.2.1.135).

Pullulan Hydrolases

Pullulan hydrolase type I (neopullulanase, 3.2.1.135, GH 13-20)

Neopullulanases hydrolyze α -1, 4- linkages of pullulan to release panose (Antranikian, 1992; Kuriki et al., 1988) and cleaves α -1, 4- and α -1, 6- linkages of starch and other polysaccharides with much less efficiency. Other amylases known to attack α -1, 4-glycosidic linkages of pullulan to form panose are *Thermoactinomyces vulgaris* R-47 α -amylases (TVA I (Tono-zuka et al., 1995) and TVA II (Tono-zuka et al., 1993)) and *Bacillus licheniformis* α -amylase (Kim et al., 1992), which efficiently hydrolyzes starch more than pullulan to release maltose as major product. These enzymes are therefore designated as neopullulanase- α -amylase (Svensson, 1994; EC 3.2.1.1/135). These are polyspecific enzymes capable of hydrolyzing at least two of the three substrates, cyclomaltodextrins, starch and pullulan, and known to catalyze transglycosylation reaction (Park et al., 2000, 2007; Nisha and Satyanarayana, 2016). The neopullulanase of *Bacillus subtilis* NA-1 forms α -1,4- and α -1,6-glycosidic linkages using maltose as the substrate by

transglycosylation (Takata et al., 1992). The neopullulanases act on starch, CDs, and maltooligosaccharides to produce large amounts of maltose and small amounts of glucose, both with an α -configuration. The activity pattern of the enzyme from *B. stearothermophilus* has been extensively studied. It catalyzes hydrolysis of both the α -1,4 and α -1,6 linkages in branched oligosaccharides. Furthermore, it catalyzes glucosyl transfer to C-4 or C-6 hydroxyl groups of acceptor sugars to form maltooligosaccharides or branched oligosaccharides such as isomaltose and panose. In this context, some of the maltogenic α -amylases (EC 3.2.1.133) have both hydrolyzing and transferring activities to form both the α -1,4 and α -1,6 linkages as described above.

Kuriki and Imanaka, based on their research on the *B. stearothermophilus* neopullulanase mutations to modify its action specificity, proposed the following concept. According to this proposal, α -amylase (EC 3.2.1.1), debranching enzymes such as pullulanase (EC 3.2.1.41) and isoamylase (EC 3.2.1.68), CGTase (EC 2.4.1.19), and a branching enzyme (EC 2.4.1.18) can be classified into a single family – the α -amylase family – based on the structural similarities and interchangeability of four reactions among these enzymes. All these enzymes share the common $(\beta/\alpha)_8$ barrel and two catalytic amino acid residues: Glu as a proton donor and Asp as a nucleophile. Additional domains present in respective enzyme groups modify the basic catalytic function of the $(\beta/\alpha)_8$ barrel to provide specificities to four enzyme groups. Enzymes of this group are produced by many *Bacillus* strains, including *B. stearothermophilus*, *Thermoactinomyces vulgaris* and other bacteria.

Pullulan hydrolase type II (isopullulanase, 3.2.1.57, GH 13-20)

Isopullulanases cleave α -1, 4- linkages of pullulan to produce isopanose (Glc α 1-4Glc α 1-6Glc) and hydrolyzes panose (Glc α 1-6Glc α 1-4Glc) to release glucose and isomaltose. The enzymes, however, do not hydrolyze starch and dextran unlike that of neopullulanases (Aoki and Sakano, 1997; Nisha and Satyanarayana, 2016), therefore, it is not included as a member of the amylase family in this article.

4- α -Glucanotransferase (EC 2.4.1.25, GH 77)

Enzymes of this group cleave α -1,4 linkages in glucan and transfer the newly formed reducing end glucose residue to the C-4 hydroxyl group of nonreducing end glucose residues. When the glucose residue is transferred to other glucan chains (intermolecular transglycosylation), the reaction results in disproportionation of glucan chains, and the plant enzyme catalyzing this reaction is often called disproportionating enzyme. Microbial enzymes with the same action specificities are sometimes called amylomal-tase. Recently, some of these enzymes were found to catalyze intramolecular transfer to form cyclic glucans consisting of only the α -1,4 linkage. The enzyme from *Thermusaquaticus* produces cycloamyloses from starch with DPs greater than 17. Besides *T. aquaticus*, microorganisms such as *Aquifexaeolicus*, *Escherichia coli*, and *Streptococcus pneumoniae* also produce this type of enzyme. Although enzymes of this group have a common $(\beta/\alpha)_8$ barrel with Glu as a proton donor and Asp as a nucleophile, they are classified as GH 77.

Branching Enzyme (EC 2.4.1.18, GH 13-9)

Enzymes of this group exist in the plant kingdom and are known to play an important role in starch synthesis. They catalyze the cleavage of α -glucan chains and the transfer of the cleaved chains to the C-6 hydroxy group of other glucan chains to form the α -1,6 branch linkage. Enzymes that can catalyze the same reaction are found in microorganisms such as *Bacillus*, *Escherichia*, and *Pseudomonas*. The enzyme from *B. stearothermophilus* was found to catalyze the intramolecular transfer reaction to form highly branched cyclic dextrins (Fig. 8(e)) from amylopectin. Enzymes of this group have the same $(\beta/\alpha)_8$ barrel structure as that of α -amylase and are classified into the GH 13-9 subfamily.

Enzymes Forming Trehalose From Starch

Two enzymes of remarkably unique specificities, maltooligosyltrehalose synthase (EC 5.4.99.15, GH 13-26) and maltooligosyl-trehalose-trehalohydrolase (EC 3.2.1.141, GH 13-10), convert starch into α -1,1'-trehalose by a cooperative process. The former enzyme acts on the α -1,4 linkage in the non-reducing end of starch or maltooligosaccharides and mutates into the α -1,1' linkage, which results in the formation of maltooligosyltrehalose. The second enzyme hydrolyzes the α -1,4 linkage adjacent to the trehalose moiety, thus releasing trehalose from maltooligosyltrehalose. Consequently, the two enzymes act on maltooligosaccharides, yielding a high amount of trehalose. These enzymes are found together in several microorganisms such as *Arthrobacter* and *Pseudomonas*. They are also found in some thermophilic archaea such as *Sulfolobus*. The industrial production of trehalose is described in a later section. Trehalose synthase (EC 5.4.99.16) catalyzes the conversion of maltose into trehalose in a manner similar to that of maltooligosyltrehalose synthase. This enzyme does not act on starch; therefore, it is not considered a member of the amylase family.

Reaction Mechanism of Amylases

As mentioned previously, most enzymes are of the retaining type of amylase, in which the α -configuration in the substrates is retained in the products. Other enzymes catalyze by means of an inverting type reaction, in which the α -configuration in the

substrates is inverted in the products. β -Amylase and glucoamylase follow the latter reaction, which yields β -maltose or β -glucose, respectively. Both types of enzymes have two acidic catalytic amino acid residues, one acting as a proton donor (general acid) and the other as a nucleophile (base).

Two theories are proposed to explain the molecular mechanisms of the two reactions: covalently bound intermediate theory and carbonium ions intermediate theory. According to the former theory, the catalytic reactions proceed via the formation of a covalently bound intermediate between substrate and enzyme protein. According to the latter theory, reactions proceed via carbonium ions without forming covalent bonds. The mechanism of the two reactions according to the covalently bound intermediate theory is depicted in Fig. 2. In the retaining reaction (Fig. 2(a)), the proton donor (general acid) donates its proton to the glycosyl oxygen, engaging the α -linkage to be cleaved, and, in cooperation with this, the nucleophile directly attacks the anomeric carbon next to the oxygen from the opposite side to form a covalently bound intermediate with a β -configuration (first Walden inversion). In the next step, the deprotonated proton donor, in turn, attacks the hydrogen in the water molecule. The activated water molecule attacks the anomeric carbon on the intermediate from the opposite side to form α -glucose (second Walden inversion). As a result of two Walden inversions, the anomeric configuration in the substrate is retained in the product. In the retaining enzyme, the water molecule is located near the proton donor in the catalytic site, whereas in the inverting enzyme, it is positioned near the nucleophile. These different positions of the water molecules in catalytic sites have been confirmed for some enzyme proteins belonging to the α -amylase, β -amylase, and glucoamylase groups, as shown below.

In the inverting reaction, the nucleophile attacks water molecules close to this residue and activates it as shown in Fig. 2(b). The activated water molecule then attacks the anomeric carbon in the substrate from the opposite side to form β -glucose. As a result, α -configuration in substrates was converted into β -configuration in the products.

Because the reaction of amylase is usually conducted in aqueous solution, the reaction is practically irreversible if a water molecule participates. Enzymes catalyzing the retaining reaction can perform a transglycosylation reaction because the covalent intermediate can be attacked not only by water but also by the hydroxyl group of sugars and alcohols. Contrary to this, enzymes catalyzing the inverting reaction do not form a covalently bound intermediate because the activated water molecule directly forms covalent bond with substrates.

(a) Retainig enzyme

(b) Inverting enzyme

Fig. 2 Illustration of retaining and inverting mechanisms. (a) Retaining mechanism. (b) Inverting mechanism. Nucleophilic residue is at the top and proton donor is at the bottom in both mechanisms. Reactions proceed from left to right.

Structure–Function Relationships of Amylases

Taka-amylase (EC 3.2.1.1, GH 13-1)

Crystal structures of Taka-amylase (α -amylase from *A. oryzae*), β -amylase, CGTase, and glucoamylase are shown in Fig. 3. They have distinct catalytic properties and distinct three-dimensional (3D) structures. The structure of Taka-amylase was determined by X-ray diffraction analysis in 1984; this was the first structure determination case in amylases. To date, more than 200 3D structures have been reported for the enzymes classified as amylases. Taka-amylase is a single peptide consisting of 478 amino acid residues, and its 3D structure is composed of three domains called A (aa 1–376), B (aa 128–201), and C (aa 385–478) as illustrated in Fig. 4. Domain A (catalytic domain) has a $(\beta/\alpha)_8$ barrel (TIM barrel) common to all enzymes of the GH 13 family, which consists of eight identical pairs of β -sheet and α -helix. Domain B is composed of three β -sheets and is inserted between the third β -sheet and the third α -helix as a short loop extruding from the large domain A. Domain C has eight antiparallel β -sheets and follows after the eighth α -helix of the $(\beta/\alpha)_8$ barrel. The catalytic site of this enzyme is located at the cleft (catalytic cleft) formed between domains A and B as shown in Fig. 3(a). This cleft has a size that can accommodate just seven glucose units of α -glucans and is gently curving to fit the helical structure of the glucans. About 20 amino acid residues are aligned on the surface of this catalytic cleft, as illustrated in Fig. 5. Two catalytic amino acid residues, Asp206 and Glu230 in the fourth and fifth β -sheets, respectively, are located near the third glucosidic linkage of the substrate. Other residues located throughout the cleft are involved in fixing glucose residues by forming hydrogen bonds with their hydroxyl group. These interactions affect substrate distortion and help the concerted hydrolytic reaction of catalytic amino acid residues. In the catalysis, Asp206 acts as a nucleophile (base), and Glu230 acts as a proton donor (acid). A water molecule is known to present near Glu230 at the catalytic site. Although most of these amino acid residues are on the $(\beta/\alpha)_8$ barrel in domain A, some are on domain B. The Ca^{2+} ion is located inside the catalytic cleft, as shown in Fig. 3(a), and coordinates with several amino acid residues, thus stabilizing the cleft architecture essential for catalytic reaction. The function of domain C is not fully understood.

Fig. 3 Crystal structures of representative amylase proteins. (a) Taka-amylase from *Aspergillus oryzae*. (b) CGTase from *Bacillus circulans*. (c) β -Amylase from *Bacillus cereus* var. *mycoides*. (d) Domain A of glucoamylase from *Aspergillus awamori*. Drawings were done based on the PDB (2TAA, 1CXE, 5BCA, 1AGM) using PyMOL program (<http://pymol.sourceforge.net/>). Helical ribbon stands for the α -helix and broad arrow stands for the β -sheet.

Fig. 4 Topological diagram of Taka-amylase. The drawing was done based on the Matsuura, Y., Kusunoki, M., Harada, W., Kakudo, M., 1984. Structure and possible catalytic residues of Taka-amylase A. *J. Biochem.* 95, 697–702 (2TAA). Circles and squares indicate α -helices and β -sheet, respectively. Numbers in these symbols indicate their sequence order in each domain. Positions of the two catalytic amino acid residues are shown within double circles and residues binding to calcium ion are shown within square brackets. Amino acids are expressed by single letters.

Fig. 5 Catalytic site structures of Taka-amylase binding acarbose glucose residues in the acarbose are numbered from the nonreducing end residue. Positioning of two catalytic residues, Glu230 and Asp206, are indicated by double circles. Residues involved in substrate binding are also shown. Amino acids are expressed by single letters.

Cyclomaltodextringlucanotransferase (Cgtase, EC 2.4.1.19, GH 13-2)

This enzyme has catalytic properties distinct from those of α -amylase; however, it is classified in the same GH 13 family. The 3D structure of CGTase from *B. stearothermophilus* strain TC-91 is shown in Fig. 3(b). It is composed of five domains: A (aa 1–403), A' (aa 136–196), B (aa 404–493), C (aa 494–576), and D (aa 577–680). Domain A has a $(\beta/\alpha)_8$ barrel, and domain A' is extruded from this barrel between the third β -sheet and the third α -helix of the barrel. Thus, domains A, A', and B of CGTase roughly correspond to the three domains of Taka-amylase. A large cleft present between the $(\beta/\alpha)_8$ barrel and domain A' forms the catalytic site (catalytic cleft). This enzyme has two calcium ions, one of which is present in the cleft, as is Taka-amylase. As in the case of the catalytic amino acid residues of Taka-amylase, Asp225 and Glu253 of CGTase are presumed to be the nucleophile and the proton donor, respectively. The structural features explaining the transglucosylation reaction of CGTase are not fully understood. Domains C and D are the structures specific for CGTase. Domain D consists of eight antiparallel β -sheets and acts as a starch-binding site, which plays an important role in the digestion of raw starch (starch granules). Domain C also contains β -sheets, although its function is not fully understood. The crystal structure of the CGTase from alkaliphilic *Bacillus* sp. 1011 with the substituted His233N revealed the change of active site conformation, such that the mutated variant does not produce α -cyclodextrin, while the wild type forms a mixture of α -, β - and γ -cyclodextrins (Ishii et al., 2000). The three dimensional structure of CGTases reveals that the Tyr/ Phe residues play an important role in the formation of CD (Leemhuis et al., 2010).

β -Amylase (EC 3.2.1.2, GH 14)

The 3D structure of β -amylase from *Bacillus cereus* is shown in Fig. 3(c). It consists of large domain A (aa 1–417) and small domain B (aa 418–516). Although this enzyme belongs to GH 14, its domain A has a $(\beta/\alpha)_8$ barrel like that of α -amylase. The catalytic site of this enzyme is formed on the barrel by the assembly of short loops present between β -sheets and α -helices. The catalytic site has a pocket-like structure, as illustrated in Fig. 6. Glu367 and Glu172 are present near the center of this pocket and serve as a nucleophile and a proton donor, respectively. A water molecule is known to be present near Glu367. A short peptide extending between the third β -sheet and the third α -helix is located around the catalytic site as a flexible loop, which is a unique structure to β -amylase. Four or five glucose units at the non-reducing end of α -glucans can enter into this pocket. The flexible loop holds the substrate tightly during catalysis and moves away to release the product (β -maltose) from the catalytic pocket after the reaction completes. The pocket-like structure of β -amylase is in sharp contrast to the cleft-like structures found in α -amylase and CGTase and explains the exo-acting style of this enzyme. Domain B has a structure similar to that of domain D of CGTase and has starch-binding activity.

Glucoamylase (EC 3.2.1.3, GH 15)

The 3D structures of glucoamylase from *A. niger* and related strains have been extensively studied. The enzyme from *A. niger* consists of three domains: domain A (aa 1–440), B (aa 441–512), and C (aa 513–616). As illustrated in Fig. 7, domain A of this enzyme has an $(\alpha/\alpha)_6$ barrel, which is clearly different from the $(\beta/\alpha)_8$ barrel found in almost all of the other enzymes listed in Table 1.

Fig. 6 Catalytic site structure of *Bacillus cereus* β -amylase. Image of pocket-like structure of catalytic site is drawn with broad solid line based on PDB(1ITC). Glucose residues in glucans are numbered from the residue at the nonreducing end. Positions of the two catalytic amino acid residues, Glu367 and Glu172, are shown with double circles. Residues involved in substrate binding are also shown. Amino acids are expressed by single letters. Image of a flexible loop in closed form is shown by a dotted line.

Fig. 7 Schematic representation of $(\alpha/\alpha)_6$ barrel in comparison with $(\beta/\alpha)_8$ barrel. (a) $(\alpha/\alpha)_6$ barrel of *Aspergillus awamori* glucoamylase. (b) $(\beta/\alpha)_8$ barrel of Taka-amylase. Circles indicate α -helices with numbers ordered from N-terminal. Large arrows indicate loops connecting outer and inner helices with numbers ordered from N-terminal. Small arrows indicate loops connecting inner and outer helices. Two catalytic amino acid residues, Glu400 and Glu179, are shown with double circles. Residues blocking one end of the catalytic cavity are shown with boxed line. Amino acids are expressed by single letters.

The even-numbered six helices form the inner core of the barrel, whereas the odd-numbered helices form the outer part of the barrel. The catalytic site (catalytic cavity) is composed of six inner α -helices and six loops connecting the C-terminal residues of the outer helices and the N-terminal residues of the inner helices. One end of this catalytic cavity is blocked off by the residue following the last inner helix, and only the opposite end is open to the substrates. Two catalytic amino acids, Glu400 in the sixth loop and Glu179 in the third loop, act as a nucleophile and a proton donor, respectively. As in the case with β -amylase, a water molecule is oriented near Glu400 during the catalytic cavity. Domain B is a linker domain rich in Ser and Thr residues. Domain C is a starch-binding domain with a sequence resembling that of the starch-binding domains in CGTase and β -amylase.

The crystal structure of the starch binding domain of *R. oryzae* glucoamylase and its complex with the substrates, β -cyclodextrin and maltoheptaose identified two carbohydrate binding sites, Trp47 and Tyr32 as well as the asparagine residues in polyN loops (Tung et al., 2008). The *Saccharomycopsis fibuligera* HUT 7212 glucoamylase, which lacks the raw starch binding domain, displayed the presence of two substrate binding sites within the catalytic domain upon crystal structure analysis of the complex of the enzyme with acarbose (Sevcik et al., 2006).

Engineering of Amylases

Directed evolution and site-directed mutagenesis have been employed upon amylases to improve their properties like activity, substrate specificity, thermal and pH stability and solubility (Rubin-Pitel and Zhao, 2006). Thermostability, Ca^{2+} -independence, raw starch degrading ability and acid stability of α -amylases are desirable for their use in the starch saccharification process, and oxidative stability as well as pH optima in alkaline range is a prerequisite for the applicability of amylases in detergent industry.

In general, enzymatic reactions are performed under moderate conditions (temperature and pH), because most enzyme proteins cannot maintain active structures under extreme conditions. However, in the industrial application of enzymes, enzymatic reactions at higher temperatures are advantageous because of the higher solubility of substrates and protection from contamination. Thus, screening of thermostable enzymes or microorganisms has been actively carried out in extreme circumstances, such as hot springs and seabed volcanoes. The enzymes are genetically engineered to generate thermostable enzymes. Random mutagenesis and gene shuffling are used most often to increase the heat stability of known enzymes. The thermostability of *Thermus* sp. maltogenic amylase, for instance, was greatly improved by four rounds of DNA shuffling. The variant of *Bacillus thermalkalophilus* ET2 maltogenic amylase formed by three rounds of DNA shuffling and the recombination of the selected mutations displayed 10°C higher temperature optimum compared to the native enzyme. One of the variants carrying substitution exhibited a 20-fold longer half-life in comparison to the wild-type (Tang et al., 2006). The maltogenic amylase, Novamyl, displayed improved thermostability (10°C upward shift in melting temperature as compared to the wild type at pH 4.0) upon triple mutation and therefore enhanced its use as an antistale for breads made at low pH (Jones et al., 2008). A significant increase in half-life was observed for

the *Bacillus* sp. TS-23 α -amylase when the deletion was made of Arg210-Ser211 sequence (Lin et al., 2008). The site directed mutagenesis of the calcium binding sites (Asn-75, Ser-76 and His-77) of α -amylase from *B. megaterium* resulted in improved thermostability (Ghollasi et al., 2013). The chimeric enzyme formed by the fusion of the *Bacillus acidicola* α -amylase and the gene fragments encoding partial N- and C- terminal region of *G. thermoleovorans* α -amylase displayed higher thermostability than the wild type *Bacillus acidicola* α -amylase (Parashar and Satyanarayana, 2016). The N- domain deletion of the maltogenic amylases of *G. thermoleovorans* and *Thermus* sp. identified its role in thermostability and substrate affinity (Mehta and Satyanarayana, 2013; Kim et al., 2001).

The protein engineering using site-directed mutagenesis resulted in a significant increase in thermostability and catalytic efficiency as well as starch saccharification efficiency in case of pullulanases from *Bacillus deramificans* (Duan et al., 2013) and *B. acidopullulyticus* (Chen et al., 2015). The N-terminal truncated *B. deramificans* pullulanase mutant displayed improved extracellular secretion and thermostability (Duan and Wu, 2015). The amylopullulanases of *T. ethanolicus* 39E (Lin et al., 2008), *T. saccharolyticum* (Lin et al., 2011), *L. plantarum* L137 (Kim et al., 2009) and *G. thermoleovorans* NP33 (Nisha and Satyanarayana, 2013a) showed an improved catalytic efficiency and thermostability by C-terminus truncation. The N- and C-terminal truncated variants of the *G. thermoleovorans* exhibited reduced random coils compared to the wild type, suggesting improved conformational and thermal stability of the enzyme with the deletion (Nisha and Satyanarayana, 2015a,b). An increased stability towards temperature and detergents was achieved by mutation of some bulkier side chain amino acids in neopullulanase of *B. stearothermophilus* (Ece et al., 2015).

Improved acid stability was achieved in case of *B. licheniformis* α -amylase, when Leu134 and Ser320 were mutated (Liu et al., 2008). In another example, single, double and triple mutations at four histidine residues (His222, His275, His293 and His310) in the catalytic domain significantly increased the acid stability compared to the wild type (Yang et al., 2013).

Specificities to the α -1,4 or α -1,6 linkages of enzymes belonging to the amylase group are generally considered to be very strict, except for glucoamylase and α -glucosidase. Recently, endo-acting enzymes such as neopullulanase and maltogenic α -amylase were shown to have specificities not only to the α -1,4 linkage but also to the α -1,6 linkage in the substrates. The specificity ratio of α -1,4/ α -1,6 of neopullulanase was modified by replacing the special amino acid residues responsible for substrate binding with other residues. Currently, creation of mutated enzymes by substituting special amino acid residues with other residues based on the 3D structures of enzymes has become one of the most popular enzyme engineering methods. Site-directed mutagenesis of the catalytic site residues resulted in the loss of *B. stearothermophilus* neopullulanase activity towards both α -1, 4- and α -1, 6- glycosidic linkages, thereby suggesting the presence of one active site for the dual activity. Further, altered substrate specificity towards α -1, 4- and α -1, 6-glycosidic linkages was observed by mutating the substrate binding sites (Kuriki et al., 1992). The protein engineering of the active subsites -3/-6/-7 altered cyclodextrin specificity of CGTases (Kelly et al., 2008a,b; Nakagawa et al., 2006).

Transglycosylation reactions of α -amylase and α -glucosidase have been widely used for the production of useful oligosaccharides. A great deal of effort has been spent on the screening of enzymes with high transferring activities. In the field of enzyme engineering, many studies on modification of the catalytic properties of enzymes such as substrate and product specificities and action modes have been reported. In some cases, successful results were obtained, with special enzymes tested. However, no versatile method of modification has had successful results. Withers and colleagues reported that a mutant of β -glucosidase (EC 3.2.1.21) from *Agrobacterium* sp., with a mutation at its nucleophilic E358, catalyzed the synthesis of various β -glycosides using α -glucosyl fluoride as a donor and various p-nitrophenyl- β -glycosides as acceptors. They called the mutated enzyme glycosynthase. By replacing one of the catalytic (nucleophile) amino acid residues with other amino acids, hydrolase was successfully changed into synthase. To date, 19 hydrolases with retaining or converting mechanisms have been converted into glycosynthases by substituting their nucleophilic residues. α -Glucosidase from *Schizosaccharomyces pombe* was successfully converted into glycosynthase using this method.

The protein engineering of the maltogenic amylase (MAG1) of *Bacillus lehensis* G1 by the mutations of the residues, W359F, Y377F, and M375I minimized steric interference and changed the active site conformation to accommodate larger donor/acceptor molecules for transglycosylation, thereby improving the transglycosylation to hydrolysis ratio of upto 4.0-fold (Manas et al., 2015). The maltogenic amylases with high hydrolysis to transglycosylation ratio are used to decrease the content of maltotriose in high maltose syrups. Transglycosylation activity of the *B. stearothermophilus* maltogenic amylase was decreased and the increased maltose production was attained by site-directed mutagenesis of the W177 residue (Sun et al., 2016). Tran et al. (2014) reported an improved transglycosylation activity by site directed mutagenesis of the His235 in the catalytic domain of the enzyme. The mutations in two residues, Ser-77 and Trp-239, on the outer region of the active site of *Thermoanaerobacterium thermosulfurigenes* cyclodextrin glucanotransferase revealed 15-fold lower hydrolytic activity over cyclization activity, while the hydrolytic rates were unaffected by mutations generated within the active site of the enzyme (Kelly et al., 2008b).

Industrial Application of Amylases

Industrial Production of Amylases

The history of the industrial production of amylase dates back to 1894, when Jhokichi Takamine began the commercial production of a digestive enzyme preparation, Taka-diastase, from a wheat bran culture of *A. oryzae*. In 1905, a textile desizing agent containing α -amylase from *A. oryzae* was produced in Japan. The industrial production of α -amylase for its application in starch liquefaction started as early as 1939 with the use of *B. amyloliquefaciens*. In 1959, *Rhizopus* sp. began to be used in the industrial production of

glucoamylase. In those days, enzymes were produced in solid culture using wheat bran, although this cultivation method was replaced with submerged cultures.

Besides α -amylase and glucoamylase, many enzymes, such as β -amylase, pullulanase, and CGTase, are commercially available from enzyme manufactures such as Novozyme, Danisco, and Amano Enzyme Inc. The value of the industrial enzyme market was estimated at USD 4.2 billion in 2014 and to reach approximately USD 6.2 billion by 2020. The starch hydrolyzing enzyme finds potential application in the preparation of HFCS (high fructose corn syrup), production of ethanol as well as in detergent and baking industries. The starch enzyme market is estimated to a value of \$2.24 billion by 2018 (see "Relevant Websites section"). Enzymes belonging to the amylase group are estimated to account for 30% of world enzyme production. Recombinant enzymes are also released in the market for industrial application. The following list shows the enzymes that are currently available for industrial applications and their origins.

α -Amylase: *A. oryzae*, *A. niger*, *B. subtilis*, *B. amyloliquefaciens*, *B. licheniformis*, *Bacillus* sp.

Glucoamylase: *A. niger*, *R. niveus*, *Rhizopus* sp.

Pullulanase: *Bacillus acidpullulyticus*, *B. brevis*, *B. licheniformis*, *Klebsiella* sp.

α -Glucosidase: *A. niger*, *B. stearothermophilus*, *S. cerevisiae*

CGTase: *B. macerans*

Maltotriohydrolase: *Microbacterium* sp.

Maltopentaohydrolase: *Bacillus* sp.

Application of Amylases in Food Industries

Starch liquefaction and saccharification

The global enzyme market was dominated by the food and beverage industry in 2010, with the major market share occupied by the baking enzymes. Starch industry approximately accounts for 15%–20% of the global sales of industrial enzymes. The industrial starch hydrolysis requires the action of different endo- and exo-acting enzymes including α -amylase, pullulanase, glucoamylase, glucose isomerase and others.

Starch, especially corn starch, is the most abundant and cheapest carbohydrate commercially available. For the production of glucose or oligosaccharides, raw starch (starch granules) is first gelatinized to disrupt the starch granules; to this, α -amylase is added to hydrolyze starch into low-molecular-weight dextrins. Thermostable liquefying α -amylase, such as that from *B. subtilis* and *B. licheniformis* is added to the starch slurry, and the mixture is heated quickly to around 100°C for a suitable period to obtain products of desired dextrose equivalence (DE). Dextrins with a DP of 3–25 are commercially produced for various applications, such as to improve viscosity or to be a filler or ingredient of food. The dextrins are then saccharified by debranching enzymes to products of DP2–5. Maltose is often used as a sweetener or to improve the quality of food. Part of the highly purified maltose is used in the medical field. For the industrial production of maltose, starch is liquefied as described above, α -amylase is inactivated by heating the solution at 120–140°C, the pH is adjusted to around 4.5, and then β -amylase and isoamylase from *P. amyloclavus* or pullulanase from *Bacillus* sp. are added. This saccharification process is run for 2 or more days at 60°C to yield a high amount of maltose. Currently, β -amylase from plants is used; however, this will be replaced by bacterial β -amylase in future. In Japan, about 3 million tons of starch is produced annually, mainly from corn. More than 60% of the starch is hydrolyzed to glucose, which is consequently converted into fructose to obtain a commercial product, high-fructose corn syrup (HFCS). More than 8 million tons of HFCS is produced annually in the United States, whereas about 1 million tons is produced annually in Japan. HFCS is a mixture of glucose and fructose and is widely used as a sweetener for beverages. Conversion of glucose into fructose is carried out by the action of glucose isomerase. This enzyme (xylose isomerase; EC 5.3.1.5) plays an important role in industrial starch saccharification; however, it cannot be classified as an amylase and, thus, will not be discussed further. Thus, production of glucose from starch is the main goal of the starch industry. The enzymatic process used to produce glucose from starch consists of two steps: liquefaction and saccharification. The starch granules are heated (gelatinized) in a jet cooker to 105–110°C for 5 min (pH 5.8–6.5) and then partially hydrolyzed (liquefaction) using *B. licheniformis* α -amylase (24,000 U g⁻¹), for example, is added to a starch slurry (30%–40%) at an enzyme–starch (dry weight) ratio of 0.6 kg ton⁻¹. Then, the mixture is kept at 90–95°C for 1–2 h to obtain a final DE of 5–15. In the saccharification step, the pH of the liquefied solution is adjusted to 4.5 and the temperature lowered to 55–60°C. The *A. niger* glucoamylase (200 AGU ml⁻¹) and *Bacillus* sp. pullulanase (200 U g⁻¹) are added at enzyme–starch (dry weight) ratios of 0.8 l ton⁻¹ and 0.3 kg ton⁻¹, respectively. The mixture is kept at 60°C for 2–3 days to obtain the final DE of 97–98.5. Most of the obtained glucose syrup is converted into HFCS, and the remaining part is purified to produce crystalline glucose. In the production of alcoholic beverages, fungal α -amylase preparations are often used to promote the digestive action of malt or Koji enzymes in the saccharification of starch. Amylase preparations are occasionally used together with pectinases in juice clarification.

The pullulanases are widely used in the industrial starch saccharification process for the production of maltose, maltotriose and maltotetraose syrups. The currently employed pullulanase in starch saccharification process increases the glucose or maltose concentration by 2% and 20%–25%, respectively and minimizes the use of glucoamylase by 50% and reduces the total reaction time (Jensen and Norman, 1984). The enzyme preparation containing both glucoamylase and pullulanase are commercially available (OPTIMAX[®] from Genencor). The acid stable, Ca²⁺-independent and thermostable amylopullulanase from extreme thermophile, *Geobacillus thermoleovorans* NP33 has potential application in the starch processing industry as these are thermostable and Ca²⁺-independent with raw starch degrading ability (Nisha and Satyanarayana, 2013a, 2014). Because of the debranching

ability and debranching action of the enzymes, thermostable amylopullulanases can be employed as biocatalysts in one-step starch liquefaction-saccharification for producing different sugar syrups by replacing amylolytic enzymes like glucoamylase and α -amylases, thereby reducing the cost of sugar production. The *G. thermoleovorans* NP33 amylopullulanase pretreated raw starches have been saccharified to a greater extent by the glucoamylase in comparison to the starch saccharification achieved with the α -amylase pretreated starches and glucoamylase alone (Nisha and Satyanarayana, 2013a, 2014). An improved thermostability and catalytic efficiency achieved with the protein engineering effort via C-terminal truncation has enabled the efficient use of the enzyme in starch saccharification. An improved thermostability and catalytic efficiency achieved with the protein engineering effort via C-terminal truncation has enabled the efficient use of the enzyme in starch saccharification (Nisha and Satyanarayana, 2013a).

Preparation of maltooligosaccharides

Maltooligosaccharides are composed of glucopyranosyl units linked by an α -1,4 linkage, while the ones containing both α -1,4 and α -1,6 glucosidic linkages are called branched oligosaccharides or isomaltooligosaccharides. According to the International Union of Pure and Applied Chemistry, linear maltooligosaccharides are defined as polymers of monosaccharides with degree of polymerization between 3 and 10. The maltooligosaccharides are widely used in beverage, food and pharmaceutical industries (Fogarty and Kelly, 1990). The amylases that efficiently produce maltooligosaccharides have gained considerable attention in the past few decades. Maltooligosaccharides are characterized by high solubility, less sweetness, low calories, less water activity, good moisture level, acid resistance and heat stability. These can be made into various healthcare and nutritional foods including baby foods, confectionary items, healthcare candies, beverages, healthcare beers and ice creams. Maltotriose, maltotetraose and maltopentaose minimize retrogradation by inhibiting realigning of amylose and amylopectin chains, thus prevent loss of moisture from starch and interfere with starch–gluten interaction; these properties make them useful as antistaling agent in the bread industry (Min et al., 1998; Nagarajan et al., 2006; Plácido Moore et al., 2005).

Maltooligosaccharide syrups serve as the feed of high nutrition to infants and the aged (Stahl et al., 2013). Maltooligosaccharides come under soluble non-digestible carbohydrates (Roberfroid and Slavin, 2000), which stimulate the intestinal microbiota, especially the bifidobacteria and form fermentation products in the colon (Nakakuki, 2002; Gibson and Roberfroid, 1995). These non-digestible oligosaccharides are called prebiotics (Mussatto and Mancilha, 2007), and are categorized as functional food ingredients which can escape from low pH stomach fluids and digestive enzymes, and are metabolized in large bowels. Maltooligosaccharides can be gradually absorbed in human body, and thus, provide energy continuously for a long period. Furthermore, maltose and maltooligosaccharides have low calories, thus regulating blood glucose levels, and decreasing post-prandial blood glucose levels (Kayode et al., 2009). Therefore, it is beneficial for the cardiovascular, diabetes and obese patients. In addition, maltooligosaccharides provide increased body endurance, immunity and induce good therapeutic effect to persons with hypoglycemia and brain disorder associated with overconsumption of energy (Zhu et al., 2011). Maltooligosaccharides are commercially available as Fuji Oligo syrups, a product of Nihon Shokuhin Kako Kogyo Kabushiki Kasha (Tokyo, Japan).

Antistaling agent in making of bread and other baked products

The amylases can be employed in the bread industry as an antistale. Staling refers to all the undesirable changes such as loss of the moisture content in the bread crumb, reduced crispness of the crust and diminished bread flavor that occurs upon storage of bread. Staling occurs because of retrogradation of the amylopectin of starch (Kulp and Ponte, 1981; Champenois et al., 1999). An antistaling agent acts by shortening the amylopectin chain. In making bread, *A. oryzae* α -amylase, for instance, is added to dough to degrade damaged starch into dextrin, which is utilized by yeast during fermentation. The increase in fermentable sugars eventually results in an increase in loaf volume. Another role of added amylase is to produce surplus amounts of maltose in the dough, some of which lasts after baking and prevents baked bread from becoming stale by interfering with the retrogradation of starch molecules on the shelf. For this purpose, plant β -amylase or maltogenic α -amylase (EC 3.2.1.133) from *B. stearothermophilus* are widely used.

The α -amylase presently used in making bread results in sticky bread when added in excess because of the production of branched maltodextrins (De Stefanis and Turner, 1981). The *G. thermoleovorans* NP33 amylopullulanase has been reported to act as an antistale, which in turn improves the shelf life of bread and other baked products (Nisha and Satyanarayana, 2014). The debranching action of amylopullulanase enables the hydrolysis of the branched maltodextrins, thereby eliminating the stickiness of the α -amylase treated bread and other bakery products. The supplementation of whole wheat dough with the *G. thermoleovorans* NP33 amylopullulanase markedly improves the quality of the bread by enhancing the shelf-life, texture of bread and the loaf volume (Nisha and Satyanarayana, 2014). Moreover the maltooligosaccharides, generated in the bread using enzymes, will act as prebiotics in ameliorating human health.

Detergent applications

The alkalitolerant amylopullulanase of *G. thermoleovorans* NP33 finds application as a detergent additive (Nisha and Satyanarayana, 2014). The enzyme exhibits significant stability in different commercially available detergents and efficiently removes the starch stain as revealed from the wash performance analysis of the stained cotton fabric. An increase in reflectance, when washed with the combination of enzyme and the detergent as compared to the detergent alone, suggested the potential use of the enzyme as detergent additive.

Preparation of cyclodextrins

Cyclodextrins are cyclic oligosaccharides with six to eight α -1, 4-linked glucose units. CDs comprising six, seven, and eight α -D-glucose residues are called α -, β - and γ -CD, respectively. CDs can form an inclusion complex with hydrophobic compounds with suitable molecular sizes and are being used in the food, pharmaceutical, cosmetic and plastic industries as emulsifiers, stabilizing agents and antioxidants. An inclusion complex with a volatile compound (allyl isothiocyanate) of wasabi (a Japanese spice) is widely used as a food ingredient to keep the volatile compound from evaporating while serving on the table. The annual production of CDs is around 2000 tons. For the industrial production of CDs, a gelatinized starch solution is incubated with cyclodextrin glucanotransferase (CGTase) from *B. macerans* in a membrane reactor using intramolecular transglycosylation (cyclization reaction). Ratios of α -, β -, and γ -CDs in the reaction product vary depending on the sources of CGTase to be used. Branched cyclodextrins possess one or more saccharide chains such as maltose linked to cyclodextrins by α -1, 6 bond (French et al., 1965). Maltosyl-CDs (CDs with maltose linked through the α -1,6 linkage) are industrially produced using a reverse reaction of thermostable pullulanase at a high concentration of maltose and CDs. Pullulanases are known to produce branched cyclodextrins. Branched cyclodextrins such as 6-O- α -maltosyl-CDs (G_2 -CDs) and 6-O- α -D-glucosyl-CDs (G_1 -CDs) are generally more soluble than linear cyclodextrins and thus result in more soluble inclusion complexes (Okada et al., 1988). The enzyme forms the condensation product of CDs with malto-oligosaccharides (Kitahata et al., 1987). Watanabe et al. (1997) used pullulanase from *Klebsiella pneumoniae* for condensation of α -CD and maltose (G_2) by reverse synthesis and the hydrolysis of the resulting Q-O- α -maltosyl- α -CD (G_2 - α -CD) by glucoamylase, which formed 6-O- α -maltosyl-CDs (G_2 -CDs) and 6-O- α -D-glucosyl-CDs (G_1 -CDs).

Preparation of resistant starch

Pullulanases have been used for improving resistant starch content (Vatanasuchet et al., 2010; Perera et al., 2010; Zhang and Jin, 2011). Resistant starch forms because of reversion of gelatinized starch to a form highly resistant to α -amylase hydrolysis (Annison and Topping, 1994). The resistant starch is fermented in the large intestine by the gut microbiota and escapes digestion in the small intestine. The resistant starches have gained importance in the health care sector as these produce short-chain fatty acids, and low levels of plasma glucose and insulin (Mun and Shin, 2006). Resistant starch functions as dietary and functional fibre based on whether these occur naturally in foods or are added. An increased ratio of the amylose/amylopectin is the most important factor in the resistant starch preparation. The linear amylose chains condense to form double helices after gelatinization as a result of its retrogradation and make the α -1, 4-glucosidic linkages accessible to amylase.

Preparation of panose and isopanose containing syrups

The pullulan hydrolase is employed for the preparation of panose and/or isopanose containing sugar syrups. These syrups act as proliferating agents of the intestinal *Bifidobacterium* and *Lactobacillus* species and are commercially used as functional foods. The panose and isopanose containing sugar syrups are being used as dietary supplements in Japan and USA (Machida et al., 1991). As compared to other prebiotic sugar syrups (lactulose), these selectively stimulate the proliferation of *Bifidobacterium* and prevent the growth of other microbes which produce harmful substances like amines and ammonia in the intestines. These are also known to display anticarcinogenic activity.

Application of Amylases in Non-Food Industries

Amylase preparations, together with other hydrolases such as β -glucanases, xylanases, and proteinases, are added to animal feed to increase the absorption efficiency of nutrients. These enzymes need to be thermostable because the feed is usually heated during manufacturing. In textile weaving, starch paste (gelatinized starch) is usually used as a sizer to provide strength to textiles. The starch must be removed from the textile before the next process, such as dyeing. Amylases facilitate the process of desizing (removal of sizing materials) without affecting the fabric quality. *B. subtilis* α -amylase is widely used for this purpose. For example, sized cloth is steeped in an α -amylase solution ($15,000$ – $40,000$ U l⁻¹) at 70 – 80°C for less than 1 min and then the enzyme and hydrolyzed products are removed by washing the cloth with hot and cold water successively. The use of hydrolases in detergents to remove stains on cloth and tableware is the biggest application field for bacterial enzymes. α -Amylases are added together with other hydrolases, such as proteinase, lipase, and cellulase, to hydrolyze starchy stains. Enzymes stable under alkaline conditions and under the presence of surfactants have been developed for this purpose. Most papers are coated with starch granules to improve their strength, stiffness, and erasability. Starch suspensions must have sufficient viscosity in the coating process, which can be achieved by adding amylase to this suspension. Because of the explosive increase in oil prices, there is a strong demand for petroleum substitutes worldwide. Increasing amounts of bioethanol are produced from starch or sucrose to meet these demands. *Saccharomyces cerevisiae* and *Zymomonas mobilis* (ethanol fermenting microbes) do not possess enzymatic system for the complete hydrolysis of starch into simple sugars, thus, they are not capable of converting starch into ethanol directly. Starch, therefore, needs to be hydrolyzed enzymatically using α -amylase and glucoamylase into simple sugars (Uma Maheswar Rao and Satyanarayana, 2007).

Discovery and Application of New Enzymes

The discovery of microorganisms (or enzymes) that convert starch directly into trehalose, by Hayashibara Biochemicals in 1990, started the industrial production of trehalose. In 2006, the annual production of trehalose reached 30,000 tons; its main

application is to improve the quality of food. Besides protecting the retrogradation of gelatinized starch, this sugar is known to have unique chemical and physiological functions. Several microorganisms, such as *Arthrobacter* sp. and *Brevibacterium helvolum*, produce two unique enzymes responsible for this conversion: maltooligosyltrehalose synthase (4- α -glucan 1- α -D-glucosylmutase, EC 5.4.99.15) and maltooligosyltrehalosetrehalohydrolase (4- α -D-glucanotrehalosetrehalohydrolase, EC 3.2.1.141), as described above.

A series of new enzymes or new actions of known enzymes, discovered recently, act on starch and produce various types of cyclic glucans (Fig. 8). Cyclic nigerosyl α -1,6-nigerose (Fig. 8(a)) is produced from starch by the cooperative action of two transferases produced by *Bacillus globiformis*: 6-glucosyltransferase (EC 2.4.1.24) and 3-isomaltosyltransferase (EC 2.4.1.-). The first enzyme is responsible for the formation of isomaltosyl residue, and the second enzyme catalyzes the formation of the α -1,3 linkage and cyclization. Another cyclic tetrasaccharide, maltosyl α -1,6-maltose (Fig. 8(b)), is produced from starch by the action of an enzyme obtained from *Arthrobacter globiformis*. This single enzyme was found to catalyze both intermolecular maltosyl transfer and intramolecular tetrasaccharide transfer. Isocyclicmaltopentaose, which has one α -1,6 linkage and four α -1,4 linkages (Fig. 8(c)), is produced from starch by a unique transferase from *B. circulans*. The enzyme isocyclomaltoligosaccharide glucanotransferase catalyzes the disproportionation reaction of maltooligosaccharides and intramolecular transfer reactions such as CGTase. However, differently from CGTase, this enzyme transfers the cleaved oligosaccharides to the α -1,6- hydroxyl group. Cycloamyloses (Fig. 8(d)), which have DPs of 17 or higher, are produced from starch by the newly discovered intramolecular transfer reactions of *T. aquaticus* amyloamylase (4- α -glucanotransferase, EC 2.4.1.25) or by a glycogen-debranching enzyme from *S. cerevisiae*, which is known to have both transferase (EC 2.4.1.25) and amylo-1,6-glucosidase (EC 3.2.1.33) activities. Highly branched cyclic dextrans (Fig. 8(e)) with narrow molecular weight distributions are produced from amylopectin by an intramolecular transfer reaction of the unique branching enzyme (EC 2.4.1.18) from *B. stearothermophilus*. Most of these cyclic sugars are commercially produced in Japan.

Fig. 8 Newly developed cyclic glucans. (a) Cyclic nigerosyl- α -1,6-nigerose. (b) Cyclic maltosyl α -1,6-maltose. (c) Isocyclicmaltopentaose. (d) Cycloamylose produced from amylose, α -1,4-glucan chain is expressed by a solid line. (e) Highly branched cyclic dextrin, α -1,4-glucan chain is expressed with circles with attached solid lines. Arrows indicate α -1,6-linked branching points.

Glossary

Antibiotic molecule of microbial origin able to inhibit the growth or to kill other microorganisms.

Antimicrobial agent substance active against microorganisms but not obligatory of microbial origin. It could be synthetic, semi-synthetic or originate from plants or mammals.

Chromosome DNA molecule which contains all the genetic information necessary for the life of the bacterium. Most often double-standed, covalently closed circular, and self-replicating.

Conjugation unidirectional transfer of genetic information (in this chapter a plasmid) involving direct cellular contact between a donor (male) and a recipient (female).

Integron DNA element that acquire open-reading frames embedded in gene cassette units and convert them to functional genes by ensuring their correct expression.

Mutation any inheritable alteration of DNA.

Operon adjacent genes co-ordinately expressed.

Plasmid minichromosome encoding accessory genetic information, such as antibiotic resistance.

Replicon DNA molecule that can replicate autonomously (chromosome or plasmid)

Resistance when a strain can grow in the presence of higher concentrations of the antibiotic compared to other strains of the same species.

Transposon (transposable genetic element) DNA segment able to migrate from replicon to replicon (plasmid or chromosome) while retaining its physical integrity. A transposon can insert into non homologous DNA, exit, and relocate independently of the general recombination function of the host.

Resistance of bacteria to antibiotics, in particular multiple resistance, has become a major health problem worldwide. Antibiotics are defined as secondary metabolites produced by microorganisms in the environment (generally the soil) active against other microorganisms because of their interaction with, and inhibition of, a specific target. In this chapter, the term “antibiotic” is used to designate natural, but also semisynthetic (e.g. certain aminoglycosides) or entirely synthetic (e.g. quinolones) molecules with antibacterial activity.

Antibiotic Classes

Antibiotics are grouped in classes (or families) on the basis of their chemical structure for examples, β -lactams (penicillins, cephalosporins), aminoglycosides (streptomycin, kanamycin, gentamicin), the tetracyclines, etc. As a consequence, members of a given class are closely related and generally share the same target in the cell and are thus substrates for the same mechanism of resistance. As we will see below, this implies that the reasoning in terms of resistance should be in classes rather than in individualized antibiotics.

The main classes of antibiotics act on four different targets (Table 1).

Inhibition of Cell Wall Biosynthesis

The cell wall protects prokaryotes from the environment and from osmolysis. The bacterial cell wall is characterized by the presence of a peptidoglycan located outside the cytoplasmic membrane; this peptidoglycan is responsible for the rigidity of the bacterial cell wall and for the determination of cell shape. Synthesis of the cell wall requires several steps in the cytoplasm, such as synthesis of the muramyl pentapeptide, which is then translocated to the external face of the cell membrane by a carrier. Crosslinking by transglycosylases and transpeptidases are responsible for the complete synthesis of the peptidoglycan outside of the cell.

The β -lactam antibiotics, such as penicillins and cephalosporins, block the transpeptidation events by binding to the transpeptidases, also named penicillin-binding proteins (PBPs).

[☆]Change History: February 2015. Authorship was changed. Authors added new text to most sections and added new references.

This article is an update of B. Périchon, P. Courvalin, *Encyclopedia of Microbiology (3rd Edn)*, edited by Moselio Schaechter, Academic Press, 2009, pp.193–204.

Table 1 Targets of the main classes of antimicrobial drugs

<i>Cell wall synthesis</i>	<i>Protein synthesis</i>	<i>DNA replication</i>	<i>Membrane</i>
Bacitracin	Aminoglycosides	Coumarines	Polymixins
β -lactams	Chloramphenicol	Quinolones	
Glycopeptides	Fusidic acid	Rifampin	
Fosfomycin	Ketolides	Sulphonamides	
	Lincosamides	Trimethoprim	
	Macrolides		
	Oxazolidinones		
	Streptogramins		
	Tetracyclines		

Glycopeptides act by binding, in a noncovalent fashion, to the C-terminal D-alanine-D-alanine dipeptide of the peptidoglycan precursors, preventing their incorporation into the growing wall.

Fosfomycin, an antibiotic active against both Gram-negative and Gram-positive bacteria, inhibits the activity of MurA, an enzyme implicated in the conversion of the nucleotide diphosphosugar UDP-*N*-acetylglucosamine to UDP-muramyl pentapeptide, by binding to its active-site cysteine and thus blocking the formation of muramyl pentapeptide. Consequently, the pool of peptidoglycan precursors is reduced.

Inhibition of Protein Biosynthesis

Bacterial ribosomes, which translate the mRNA in amino acid sequences, are constituted of two subunit nucleoprotein particles, named 50S and 30S. The large 50S subunit contains proteins and two rRNA, 23S and 5S, whereas the small 30S subunits are composed of proteins and of the 16S rRNA. The translation events start with the binding of mRNA to the 30S subunit. A formylmethionyl-tRNA is then attached to the peptidyl donor (P) site face of the AUG initiator codon. The 50S subunit is then added, and the adequate aminoacyl-tRNA enters the aminocyl receptor (A) site which is adjacent to the P site. A specific peptidyl transferase mediates a peptide bond between the *N*-formylmethionine and the adjacent amino acid.

Macrolides, such as erythromycin, bind to the 23S rRNA, near the peptidyl transferase center, block the entrance of the ribosomal tunnel, and thus stop the elongation of the peptide chain.

Tetracyclines bind in the vicinity of the A site of the 30S subunit and block the moving of the tRNA along the ribosome that impede the formation of the first peptide bond.

Chloramphenicol binds to the A site and prevents binding by tRNA.

Lincosamides (lincomycin and clindamycin), by interacting with both, the A-site and P-site, inhibit peptide bond formation.

The ribosome is also the specific target of aminoglycosides that act by causing translational errors and by inhibiting translocation.

Inhibition of DNA Replication

Topoisomerases are essential for cell viability. DNA gyrase is implicated in the control of DNA topology, in DNA replication, recombination and transcription. Topoisomerase IV is involved in DNA replication and decatenation of the chromosome. Interaction of quinolones with enzyme-bound DNA complexes is responsible for conformational changes and accumulation of complexes that could block the replication fork.

Rifampin is a RNA polymerase inhibitor that hinders protein transcription of DNA into mRNA.

Other Targets

Folic acid is an essential precursor in nucleic acid synthesis. Trimethoprim-sulfamethoxazole inhibit the folic acid metabolism pathway: the first molecule blocks the dihydrofolate reductase (DHFR), an essential enzyme for DNA synthesis, whereas the second blocks the dihydropteroate synthase.

Polymixins increase the permeability of the cell membrane.

Antibiotic Resistance

There are two major types of resistance to antibiotics: intrinsic and acquired.

Intrinsic Resistance

Intrinsic (or natural) resistance is present in all the bacteria of a given species or genus and could thus be better considered as insensitive rather than resistant. Intrinsic resistance delineates the spectrum of activity of an antibiotic. This type of resistance could

be the result of the physiological characteristics of the bacterial species or of the presence of a structural gene. Natural resistance is often due to (i) inaccessibility of the target by antibiotics, (ii) low affinity of the antibiotics for the target or (iii) absence of the target. For example, presence of an external membrane in Gram-negative bacilli (such as *Escherichia coli*) leads to resistance to various drug classes by impermeability (glycopeptides, macrolides, lincosamides, streptogramins, etc.).

Pseudomonas aeruginosa is a typical organism that exhibits a high broad substrate range intrinsic resistance resulting from a particularly low permeability of its outer-membrane associated with a number of endogenous multidrug efflux systems (such as MexAB-OprM and MexXY-OprM) and a chromosomally encoded β -lactamase (AmpC).

Enterococcus faecium produces an intrinsic low-affinity penicillin-binding protein (PBP 5) responsible for high-level resistance to cephalosporins, oxacillin, and monobactams and for an increase in resistance to the penicillins and carbapenems. *Enterococcus* spp. are also intrinsically resistant to low-levels of aminoglycosides, due to inefficient uptake of this class of antibiotics. As already mentioned, glycopeptides, vancomycin and teicoplanin, inhibit cell wall synthesis in Gram-positive bacteria by binding to the C-terminal D-alanyl-D-alanine (D-Ala-D-Ala) residues of late pentapeptide peptidoglycan precursors. *Enterococcus gallinarum* and *E. casseliflavus*-*E. flavescens* are intrinsically resistant to low-levels of glycopeptides by synthesis of modified peptidoglycan precursors ending in D-Ala-D-serine (D-Ala-D-Ser), for which glycopeptides have a low affinity, and elimination of the D-Ala-D-Ala ending precursors. These two concomitant events are due to a chromosomally-encoded *vanC* gene cluster.

Resistance to both β -lactams and cyclines in Mycobacteria is due to the combination of reduced permeability of the bacterial cell wall, presence of modifying enzymes, and low affinity for the target (such as PBP and DNA gyrase).

Acquired Antibiotic Resistance

Acquired resistance is present only in some strains of the same species or genus. In certain instances, it can be highly prevalent such as, for example, penicillinase production in staphylococci that is present in more than 90% of the strains. Intrinsic and acquired resistances do not differ in their mechanisms; both can employ the four major pathways depicted in Figure 1.

Mechanisms of Resistance

From a biochemical point of view, bacteria have developed four major mechanisms of resistance (Figure 1): (1) modification of the target; which leads to loss or decrease affinity of the drug for its target or synthesis of a new target; (2) production of an enzyme that will inactivate or modify the drug; (3) impermeability, in particular by loss of a porin (pore in the external membrane) or by diminution of its diameter in Gram-negative bacteria, and (4) efflux of antibiotics outside of the cells by energy dependent pumps.

Alteration or Synthesis of a New Target

A mechanism frequently used by bacteria to prevent the action of antimicrobial agents is the alteration of specific targets that have a necessary role in microbial growth. Target modification often results in decreased affinity for the drug. Enzymes involved in several steps of peptidoglycan synthesis, such as PBPs, or assembly represent targets of choice for antibiotics. Alteration of PBPs resulting in low-affinity for β -lactams or acquisition of new PBPs are responsible for β -lactams resistance. As an example, resistance to this antibiotic class in *Streptococcus pneumoniae* is mainly due to alteration of PBPs. *S. pneumoniae* has six PBPs (1a, 1b, 2a, 2b, 2x, and 3) in which point mutations could be responsible for β -lactam resistance in mutants obtained *in vitro*. In clinical isolates, resistance is

Figure 1 Major mechanisms of resistance to antibiotics. From top, counterclockwise: alteration of the target; production of an enzyme inactivating the drug; impermeability by mutation in a porin channel; impermeability by active efflux of the drug.

due to low-affinity variants of PBPs 2b, 2x, and 1a that are encoded by mosaic genes that result from DNA acquisition by transformation from related species of streptococci that are intrinsically less susceptible to β -lactams followed by homologous recombination. Genesis of these mosaic PBP genes is facilitated by the fact that *S. pneumoniae* is naturally transformable. Competence, which is the ability to take up DNA from the environment is due in *S. pneumoniae* to a specific protein, the competence-stimulating peptide (CSP), that acts as a pheromone. In response to a certain population density, the production of CSP is increased by the upregulation of the *comC* or *comA* gene. A typical example of a mosaic-PBP-mediated resistance is the mosaic PBP 2x which is the result of the replacement of a portion of PBP 2x of *S. pneumoniae* by the corresponding portion of the gene from *Streptococcus oralis* or *S. mitis*. This mosaic PBP 2x is more resistant to cefotaxime, despite the fact that the donor strain and the recipient *S. pneumoniae* were cefotaxime susceptible. Other mosaic structures responsible for synthesis of low-affinity PBP variants have been described (PBP 1a, 1b, 2a and 2b). Alteration of three or more PBPs are found in highly resistant isolates.

High-level resistance to methicillin and all other β -lactams in *Staphylococcus aureus* (Methicillin Resistant *S. aureus* strains, MRSA) is due to acquisition of a gene, *mecA*, responsible for synthesis of a new PBP, PBP2a, with reduced affinity for β -lactams. In the absence of *mecA*, low-level resistance could be due to overproduction of PBP4 or to modification of PBP2.

Acquired resistance to glycopeptides in *E. faecium* and *E. faecalis* detected in 1986 is due to acquisition of operons encode enzymes producing modified peptidoglycan precursors terminating in D-Ala-D-lactate (D-Ala-D-Lac) (VanA, VanB, VanD, VanM, and VanO-type resistance) or in D-Ala-D-Ser (VanC, VanE, VanG, VanL, and VanN-type). Interestingly, the base composition mol% G + C of the genes in the *van* operons suggest that these clusters are composed of genes from various sources (Figure 2). The first clinical isolates of MRSA that have acquired a *vanA* gene cluster were detected in 2002. Vancomycin resistance in vancomycin-intermediate *S. aureus* (VISA strains) is not due to acquisition of a *van* gene cluster but to synthesis of a thicker cell wall that traps vancomycin, leading to a reduced number of molecules that reach the transglycosylase targets located in the cytoplasmic membrane.

Since most ribosome-targeting antibiotics interact with rRNA, nucleotide mutation of rRNA can lead to resistance by alteration of the conformation of the drug-binding site. Due to the presence of multiple copies of rRNA operons in most bacteria, high-level resistance requires mutation in most of these operons.

The macrolide, lincosamide and streptogramin B antibiotics act by binding to the 50S ribosomal subunit and thus prevent protein synthesis. Resistance to these molecules is due to the methylation of an adenine residue (A2058 in *Escherichia coli*) in 23S rRNA by a methyltransferase specified by an *erm* (erythromycin ribosome methylation) gene. Addition of a methyl group reduces the affinity of the rRNA for these three groups of antibiotics that have very different structures. Enzymatic methylation of 16S rRNA by other methylases such as those of the Rmt family (RmtA, B, C, D, D2, E, F, G, and H), NpmA, or ArmA confer high level resistance to aminoglycosides. Rmt enzymes and ArmA methylate residue G1405 and confer resistance to the 4,6-disubstituted 2-deoxystreptamine (DOS), such as amikacin, tobramycin, arbekacin, and gentamicin, whereas NpmA methylates residue A1408 and confer resistance to the 4,6-disubstituted DOS and to the 4,5-disubstituted DOS, such as neomycin, and apramycin. RmtB and ArmA seem to be the predominant 16SrRNA methyltransferases.

Monomethylation of A2503 of the 23S rRNA confers resistance to chloramphenicol, lincosamides, oxazolidinones, some macrolides, and streptogramin A antibiotics.

Mutations in ribosomal proteins are also responsible for antibiotic resistance. For example, macrolide resistance could be due to mutations of L22 protein.

Alteration of the targets of fluoroquinolones type II topoisomerases, DNA gyrase and topoisomerase IV, constitute the main mechanism of resistance to these antimicrobial agents. These two enzymes, implicated in bacterial DNA synthesis, are composed of two subunits (GyrA and GyrB for DNA gyrase and ParC and ParE for topoisomerase IV). Mutations in a specific region of these subunits, the QRDR (Quinolone Resistance Determining Region), prevent the fixation of the quinolones on the DNA-enzyme complex. The levels of resistance conferred by mutations in the subunits of DNA gyrase or topoisomerase IV depend both on the bacterial species and the quinolone. The primary target is the DNA gyrase in Gram-negative bacteria and topoisomerase IV in Gram-positive bacteria. Mutations in the GyrA or ParC subunits are more common than mutations in GyrB or ParE. Another resistance mechanism to fluoroquinolones is mediated by the plasmid-borne *qnr* (quinolone resistance) gene. The Qnr gene product, which belongs to the pentapeptide repeat family, protects gyrase and topoisomerase IV from quinolone inhibition by binding these enzymes directly. To date, three types of *qnr* genes have been described, *qnrA*, *qnrB*, and *qnrS*. Within each type, several variants have been reported.

Antibiotics of the rifamycin family, such as rifampin, interact with the β subunit of RNA polymerase, which is encoded by the *rpoB* gene, and block transcription initiation. Mutations, including point mutations, insertions, and deletions, responsible for rifampin resistance are located in highly conserved regions, notably between the residues 507–534. Mutations in *rpoB* have been detected in mycobacteria, *S. pneumoniae*, *S. aureus*, and *Neisseria meningitidis*.

Mutations in the *dhfr* gene, encoding a dihydrofolate reductase, are responsible for trimethoprim resistance in staphylococci.

Alteration of other targets, such as iso-leucyl-tRNA synthetase, elongation factor G (EF-G), or NADH-enoyl-ACP-reductase/ β -ketoacyl-ACP-synthase are responsible for resistance to mupirocin, fusidic acid, and isoniazid, respectively.

Enzymatic Modification

This is a major mechanism of resistance to antibiotics such as β -lactams, macrolides, aminoglycosides, and chloramphenicol.

The most important antibiotic resistance mechanism in Gram-negative bacteria is due to β -lactamases that hydrolyze the four-membered β -lactam ring in penicillins, cephalosporins, carbapenems, and monobactams. The enzymes can be classified in a

Figure 2 Comparison of the *van* gene clusters. Comparison of the D-Ala-D-Lac (A) and DALa-D-Ser (B) type *van* operons. Arrows indicate coding sequences and sens of transcription.

number of ways, such as by their amino acid sequences or by their enzymatic activity spectrum. In the latter classification, four groups have been defined: : group 1, cephalosporinases on which the β -lactamase inhibitor clavulanic acid has a weak activity; group 2, penicillinases sensitive to clavulanic acid and extended spectrum β -lactamases; group 3, metallo- β -lactamases; and group 4, other β -lactamases weakly sensitive to clavulanic acid.

The macrolide esterases, such as EreA and EreB, inactivate macrolides by cleaving the macrocycle ester.

The transferase group (phospho-, nucleotidyl-, acetyl-, thiol-, ADP-ribosyl, and glycosyl-transferases) constitute a large family of modifying enzymes. The phosphotransferases catalyze the transfer of a phosphate group (generally from ATP) to a substrate. The aminoglycoside phospho-transferases (APH) confer a higher level of resistance than aminoglycoside acetyl-transferases (AAC) or aminoglycoside nucleotidyl-transferases (ANT). Depending on the aminoglycoside modification, more than fifty antibiotic-inactivating enzymes have been reported. Furthermore, various aminoglycoside inactivating enzymes can be present in the same

host. A remarkable example of this co-existence is the bifunctional enzyme AAC(6')-APH(2''), which is the fusion product of two genes and possesses an acetyl and a phosphatase activity in the same protein. This enzyme is responsible for high-level resistance in Gram-positive bacteria to all the aminoglycosides, except streptomycin and spectinomycin. Resistance to chloramphenicol is due to a large variety of chloramphenicol acetyltransferases, which are widely distributed among bacterial pathogens of all genera. Fosfomycin is modified by thiol transferases such as FosA, FosB, or FosX. FosA, found in Gram-negative bacteria, is present on the chromosome of *P. aeruginosa* whereas FosB is found in Gram-positive bacteria and, notably, on the chromosome of *Bacillus subtilis*. Three genes, *mph(A)*, *mph(B)*, and *mph(D)*, encoding macrolide 2'-phosphotransferases have been reported in *E. coli* and *Pseudomonas*.

Reduced Uptake of Antibiotics

Gram-negative bacteria possess an outer membrane (OM) external to the peptidoglycan and composed of the lipopolysaccharide (LPS) and phospholipids. This OM functions as an effective barrier, the LPS being responsible for impermeability of the OM to many molecules. Thus, some outer membrane proteins (Omp), also called porins and acting as aqueous channels, are used by several antibiotics, such as β -lactams, chloramphenicol, or fluoroquinolones, to permeate the OM. Resistance to these families of antibiotics could be due to the diminution of the porin copy number or reduction in the size of the pore.

The outer membrane of *P. aeruginosa* has a very low permeability to small hydrophilic molecules, allowing resistance of this organism to fluoroquinolones. Resistance to imipenem in *P. aeruginosa* is caused by a loss of the OprD porin in response to exposure to this antibiotic. Other antibiotic resistances associated with loss of a porin have been documented in *S. marcescens*, *E. coli*, *Enterobacter aerogenes*, *E. cloacae*, *K. pneumoniae* . . .

Increased Efflux of Antibiotics

Chromosomally encoded efflux pump could be responsible for intrinsic resistance to different class of antibiotics, initially suspected to be the effect of the OM, and consequently of reduced permeability. The widespread active export or efflux of antibiotics outside bacteria limits intracellular accumulation of toxic compounds such as antibiotics. This mechanism is mediated by the activity of membrane-based efflux proteins acting as pumps. Efflux pumps are present in the chromosome of all organisms and may have a narrow (such as tetracycline pumps) or a broad specificity, the latter conferring a multidrug resistance (MDR) phenotype to chemically and structurally unrelated compounds. Generally, drug-specific efflux pumps are encoded by mobile genetic elements, whereas MDR efflux pumps are specified by the chromosome. To date, five families of MDR efflux systems have been described: the Major Facilitator Superfamily (MFS), the ATP-binding cassette (ABC), the Resistance-Nodule-cell Division (RND), the Small Multidrug Resistance (SMR) and the Multidrug And Toxic compound Extrusion (MATE) (Table 2).

Drug efflux systems act in an energy-dependent manner by using ATP hydrolysis (ABC) or an ion antiport mechanism (MFS, RND, SMR, and MATE). The expression of multidrug transporters is commonly controlled by specific regulatory proteins. Antibiotic resistance in an efflux mutant is due to overexpression of an endogenous pump or to a mutation in a protein pump that enhance the potential of export of this protein.

As opposed to ABC transporter that usually mediates the export of specific antimicrobial classes, the MFS, RND, SMR, and MATE pumps, also designed as secondary drug transporters, are generally responsible for resistance to multiple antimicrobial agents.

Efflux pump specific for one substrate

Tetracyclines inhibit protein synthesis by preventing the attachment of aminoacyl-tRNA to the ribosomal acceptor site. Tetracycline-specific efflux pumps, which are members of the MFS family, are found in both pathogenic Gram-negative and -positive bacteria. The *tet* efflux genes code for membrane-associated proteins that reduce the intracellular drug concentration and thus protect the ribosome. Most of the *tet* determinants are found on mobile elements.

Macrolides also inhibit bacterial growth by binding to ribosomes. Efflux is also implicated in macrolide resistance. The *mef* genes, initially described in *S. pneumoniae* and *S. pyogenes*, are implicated in the specific efflux of 14- and 15-membered macrolides.

Table 2 Typical substrates of the five classes of antibiotic efflux pumps

MFS	RND	SMR	MATE	ABC
Aminoglycosides	Aminoglycosides	Aminoglycosides	Aminoglycosides	Aminoglycosides
Chloramphenicol	β -lactams	Chloramphenicol	Fluoroquinolones	Chloramphenicol
Erythromycin	Chloramphenicol	Erythromycin		β -lactams
Fluoroquinolones	Erythromycin	Tetracyclines		Erythromycin
Lincosamides	Fluoroquinolones			Fluoroquinolones
Novobiocin	Novobiocin			Lincosamides
Rifampin	Rifampin			Macrolides
Tetracyclines	Tetracyclines			Novobiocin
	Trimethoprim			Tetracyclines

The *msr(A)/msr(B)* and *msr(C)* genes, detected in *Staphylococcus* spp. and *E. faecium*, respectively, are responsible for macrolide/streptogramin efflux.

The *cmlA* genes, which are also widespread among Gram-negative bacteria, encode exporters of the MFS family that confer chloramphenicol resistance.

Efflux pump associated with multiple drug resistance

Major facilitator superfamily

Overproduction of NorA, a chromosomally-encoded protein of the MFS family, is responsible for quinolone resistance in *S. aureus*. NorA is homologous to Bmr of *Bacillus subtilis* and PmrA of *S. pneumoniae*, the latter being responsible for an increase of the norfloxacin MIC. A fluoroquinolone efflux gene, named *qepA* and located on a plasmid detected in *E. coli*, specifies an MFS transporter that confers low level of resistance to hydrophilic quinolones norfloxacin and ciprofloxacin.

An efflux pump, Tap, conferring resistance to aminoglycosides and the tetracyclines, has been detected in mycobacteria, such as *Mycobacterium fortuitum* and *M. tuberculosis*.

The chromosomal-encoded efflux pump EmrAB confers in *E. coli* resistance to nalidixic acid and to other toxic compounds. An homologous pump, VceAB, was found in *Vibrio cholerae*, a Gram-negative enteric pathogen.

An endogenous gene of *Listeria monocytogenes*, *lde*, encodes a protein of the MFS family is responsible for fluoroquinolone resistance.

Multidrug and toxic compound extrusion

Two homologous pumps, NorM (*V. parahaemolyticus*) and YdhE (*E. coli*), are implicated in fluoroquinolone and aminoglycoside resistance.

Small multidrug resistance

Substrates of these smallest multidrug resistance pumps, detected in *S. aureus* (Smr), *E. coli* (EmrE), include disinfectants and antiseptics. Genes coding for QacE and QacEΔ1, responsible for quaternary ammonium compounds resistance, are found in Gram-negative and in both Gram-negative and -positive bacteria, respectively, and are located in integrons.

ATP-binding cassette

Most bacterial ABC drug transporters are implicated in the export of specific antibiotics and have been described in various species. Expression of *lmrA* from *Lactococcus lactis* in *E. coli* is responsible for resistance to aminoglycosides, lincosamides, macrolides, quinolones, streptogramins, tetracyclines, and chloramphenicol. Similarly, the *E. faecalis* *efrAB* gene is responsible for norfloxacin and ciprofloxacin resistance; expression of *vcaM* of *Vibrio cholerae* renders bacteria resistant to tetracycline, norfloxacin and ciprofloxacin.

Resistance-nodule cell division

The RND family constitutes the most important multidrug efflux systems for clinically important antimicrobials. RND systems, composed of an inner membrane protein (RND pump) linked by a membrane fusion protein (MFP) to an outer membrane factor (OMF), are able to extrude a wide range of substrates, often unrelated in structure, from the cytoplasm to the environment.

In addition to intrinsic resistance by impermeability, *P. aeruginosa* also expresses efflux systems of the RND family. As already mentioned, some of them (such as MexAB-OprM or MexXY-OprM), participate in the intrinsic resistance. MexAB-OprM contributes to resistance to quinolones, chloramphenicol, β-lactams, novobiocin, trimethoprim, macrolides, tetracycline, and the biocide triclosan. The MexCD-OprJ system is implicated in fluoroquinolone resistance but also accommodates β-lactams, chloramphenicol, macrolides, tetracycline and trimethoprim.

In *E. coli*, the AcrAB-TolC system is homologous to MexAB-OprM. Substrates of AcrAB-TolC include macrolides, chloramphenicol, fluoroquinolones, tetracycline, rifampin, lipophilic β-lactams, fusidic acid, ethidium bromide and triclosan. AcrD and AcrEF also encode efflux pumps. AcrA, B, D, and F are also present in the *Salmonella enterica* genome.

In *Acinetobacter baumannii*, overexpression of AdeABC, a RND tripartite efflux pump, is responsible for resistance to aminoglycosides and decreased susceptibility to chloramphenicol, fluoroquinolones, erythromycin, tetracycline, trimethoprim, meropenem, and the dye ethidium bromide. Expression of the *adeABC* operon is regulated by a two-component regulatory system, *adeRS*. Mutations in *adeR* or *adeS* are responsible for the constitutive expression of the AdeABC pump, which is otherwise cryptic in wild-type *A. baumannii*. Two other efflux systems have been described in *A. baumannii*. AdeIJK contributes to intrinsic resistance to β-lactams, fluoroquinolones, tetracyclines, tigecycline, lincosamides, rifampin, chloramphenicol, cotrimoxazole, novobiocin, and fusidic acid and is regulated by AdeN, a TetR-type protein. AdeFGH confers, when overexpressed, high-level resistance to fluoroquinolones, chloramphenicol, trimethoprim, and clindamycin and decreased susceptibility to tetracyclines, tigecycline, and sulfamethoxazole. AdeFGH is regulated by a LysR-type transcriptional regulator, AdeL.

Active efflux is generally responsible for low-level antibiotic resistance. High-level of resistance is most often due to the combined effect of the impermeability of the outer membrane and of the active efflux of the antibiotics. However, intrinsic resistance is not only due to these two mechanisms. It has been demonstrated that in certain pathogens, such as *Acinetobacter baylyi*, *P. aeruginosa*, *E. coli*, and *S. aureus*, the intrinsic resistance could be associated with other chromosomally encoded elements implicated in various cellular functions.

Acquisition of Resistance

On a genetic point of view, resistance can be acquired by two totally distinct events. Either occurrence of a mutation in the genome leading to vertical inheritance of resistance to the progeny of the bacterium or acquisition of foreign genetic information, from other bacteria, by horizontal transfer.

There is a multiplicity of definitions of resistance and we have already considered the intrinsic and acquired types. Genetic resistance when the daughter cell differs from the parental cell by a genetic event (following a mutation or horizontal acquisition of genetic information). Biochemical, in bacteria that differ by the presence or the absence of a resistance mechanism. Microbiologic, when a strain can tolerate a significantly higher concentration of antibiotic (generally expressed as the Minimal Inhibitory Concentration, MIC in mg/L). Clinical, which is based on the clinical outcome: success or failure of antibiotic therapy in a patient suffering from a bacterial infection. For the sake of clarity, we will consider only the genetic dimension of resistance; in other words, the resistant bacterium (daughter cell) has suffered a genetic alteration relative to its parent (mother cell).

Biochemistry of Resistance

Cross-Resistance

Cross-resistance corresponds to resistance to all the antibiotics belonging to the same class due to a single mechanism. As we have seen above, drugs assigned to a same class are chemically related, have thus the same target of action in the cell, and are therefore subject to cross-resistance: bacteria that are resistant to one member of the class are generally resistant to the other members. However, there are degrees in cross-resistance: the more active the drug, the lower level of resistance. In general, drugs recently developed are more active than old molecules of the same class. For example, among quinolones, ciprofloxacin is much more active than nalidixic acid. As a consequence, Gram-negative bacteria that have suffered a mutational event in the target of quinolones, the type II topoisomerases (DNA gyrase and topoisomerase IV) become much more resistant to nalidixic acid (that has high MICs) than to ciprofloxacin (which retains lower MICs). This observation stresses that a resistance mechanism has no absolute value. The level of resistance also depends on the degree of susceptibility of the host bacterium. Resistance by a given mechanism will be much higher if the bacterial species is poorly susceptible. For example, the same mechanism will confer to *Pseudomonas aeruginosa*, a species naturally poorly susceptible to antibiotics, a resistance level much higher than in *Neisseria meningitidis*, a species exquisitely susceptible to drugs. Importantly, cross-resistance implies cross-selection: use of a given antibiotic can select resistance to other members of the class but not to drugs belonging to other classes.

Co-Resistance

In co-resistance, various mechanisms are associated in the same bacterial host, sometimes stabilized by integration into the genome. Each confers (by cross-resistance) resistance to a class of antibiotics which, *in fine*, can result in a broad spectrum of resistance (multidrug resistance). Again, the consequence of co-resistance is co-selection. Use of a member of a drug class can co-select resistance to another class of antibiotics with a totally distinct mode of action. This is, for example, the case for *Streptococcus pneumoniae* (Table 3).

In France in 1999, among clinical isolates of pneumococci, 46% of the strains were susceptible to penicillin G whereas 54% were resistant to this antibiotic. If one compares the rates of resistance of these two groups of bacteria to other drug classes (two top lines of Table 3), it is apparent that the strains resistant to penicillin G are much more often resistant to the other classes of antibiotics. If now one considers exclusively the penicillin G resistant strains (considered as 100%, left column in Table 3), one realises that resistance to other classes of antibiotics is extremely high. For example, administration of the combination trimethoprim-sulfamethoxazole (Bactrim®, the antibiotic most prescribed worldwide) has 88% chances to co-select a pneumococcus strain resistant to penicillin G, although these two drugs have totally different structures and targets of action.

Table 3 Antibiotic resistance in *S. pneumoniae*

S. pneumoniae (%)	Resistant to (%)				
	PenG	Em	Cm	Tc	Tp-Su
Pen ^S (46%)	0	20	14	15	10
Pen ^R (54%)	100	80	38	51	66
Em ^R	82	100			
Cm ^R	77		100		
Tc ^R	80			100	
Tp-Su ^R	88				100

Cm, chloramphenicol; Em, erythromycin; PenG, penicillin G; R, resistant; S, susceptible; Su, sulfonamides; Tc, tetracycline; Tp-Su, trimethoprim-sulfamethoxazole (Bactrim).

Figure 3 Model for site-specific gene cassette integration-excision in an integron. *attI*, Attachment site of the integron; *attC*, attachment site of the cassette; *intI1*, gene for the integrase; *Int*, integrase; P_{ANT} , outward-oriented promoter for the cassettes. Horizontal arrows indicate sense of transcription (after D. Mazel).

Integrations are a most efficient way to achieve co-resistance (Figure 3). These elements, that represent a very elegant genetic system for capture and expression of resistance genes, are not mobile and spread using mobile elements. Integrations, that can be located either in the chromosome or in plasmids, are composed of genes that have been acquired by site-specific recombination. They possess the machinery necessary to capture exogenous genes: an integrase (*intI*) that allows recombination of circularized DNA (gene cassettes), a recombination site (*attI*), and a promoter (P_{ant}) that directs transcription of the captured genes. The resistance gene cassettes inserted in the integron contain a single gene and, downstream from it, a specific *attC* site, which is an imperfect inverted repeat. In presence of the integron-encoded integrase, a gene cassette containing *attC* inserts by site-specific recombination at the *attI* site and the gene is transcribed from the P_{ant} promoter. After integration of a gene cassette, another one can be inserted at the *attI* site. This integrative process is reversible. There is a clear relationship between the position of a cassette in the integron and the level of resistance: the closer of P_{ant} , the higher level of expression of the resistance gene. To date, five classes of integrons implicated in the dissemination of antibiotic-resistance genes have been reported. Class 1 integrons, in which most of the antibiotic-resistance-gene cassettes can be found, have been detected in many Gram-negative and, less frequently, in Gram-positive bacteria. Gene cassettes in class 1 integrons confer resistance to β -lactams, aminoglycosides, erythromycin, chloramphenicol, trimethoprim, fosfomycin, lincomycin, and antiseptics of the quaternary-ammonium-compound family. The resistance determinants are tightly linked, because they are not only adjacent, but co-expressed from the same promoter. Since the genetic organization of integrons results in co-expression of the genes that have been integrated, use of any antibiotic that is substrate for one of the resistance mechanisms will co-select for resistance to all the others. The emergence of new gene cassettes in class 1 integrons, such as *qnr* implicated in resistance to fluoroquinolones, is of concern.

Extended Cross-Resistance

This type of resistance is due to a single mechanism (we are therefore dealing with cross-resistance) that can confer resistance to various drug classes and is thus designated as “extended” cross-resistance. As in co-resistance, but with differences in genetic and biochemical organization, a class of antibiotics can select for resistance to other drug classes. A typical example is the methylation of a specific adenine residue in 50S rRNA that confers high-level resistance to macrolides, lincosamides, and streptogramins B although these three classes have different chemical structure.

Another example of this type of resistance is overexpression of efflux pumps that can have very broad substrate ranges. The pumps, that are grouped in superfamilies, use energy provided by the proton motive force or hydrolysis of ATP. In Gram-negative bacteria the RND pumps can export a large array of antibiotic molecules, with very different structures, but also biocides such as triclosan. This accounts for the fact that detergents, that are increasingly used in house hold products, can select multiresistant bacteria. The pumps should be considered as the kidneys of the bacteria since they export molecules that are toxic, in particular products of the cellular catabolism. The chromosomal structural genes for the pumps are positively or negatively regulated and are generally expressed at low level. A mutation in one of the genes involved in regulation (activator, repressor, or two-component regulatory system) or in the operator will result in overexpression of the pump and to resistance to its various substrates. Thus, the smallest genetic event, a point mutation, can lead in one step to resistance to a large set of antibiotics, the so-called multidrug resistance.

Figure 4 Schematic representation of the bacterial genome.

Genetics of Resistance

The genome of bacteria is constituted of the chromosome and of mobile genetic elements such as plasmids and transposons (Figure 4). Antibiotic-resistance genes can spread using these structures but also using insertion sequences, integrons, and other complex structures such as genomic islands, integrative conjugative (ICE) and mobilizable elements (IME). The chromosome contains all the genetic information required for the life cycle of the bacteria. In general, the chromosome is not self-transferable horizontally to other bacteria. Chromosomal resistance genes and mutated genes involved in drug resistance, are inherited vertically by the next generation of bacteria. Plasmids and transposons encode functions that are not strictly required for bacterial life but that can provide advantages to the host. Antibiotic resistance genes are only transiently useful to bacteria and it thus makes sense that they are often transferable and part of mobile genetic elements. In fact, any gene can be part of a volatile structure as long as it provides intermittent selective advantage to the host and that adequate selective pressure exerts. These mobile genetic elements can be inherited horizontally and vertically.

Plasmids

Plasmids are extrachromosomal elements that can be transferred laterally by conjugation or by mobilization. They may carry resistance to several antibiotics. Conjugative plasmids are self-transferable from cell to cell by conjugation, a mechanism that requires physical contact between the donor and the recipient bacterium (Figure 5). Mobilizable plasmids can be transferred with the help of a conjugative plasmid co-resident in the same cell. A plasmid can carry multiple, easily up to seven, resistance determinants. Because of this physical linkage, selection for resistance to any of them will lead to co-transfer of the others. Thus in a single genetic event, conjugation, a bacterium can acquire “en bloc” a multiplicity of resistances.

Figure 5 Schematic representation of plasmid conjugation. Bottom, donor bacterium; top, recipient bacterium. The chromosomes are represented in a condensed state. After a single nick on one of the two complementary DNA strands, one strand is transferred from the donor to the recipient. During this process, the complementary strand of the remaining DNA strand in the donor is synthesized while the complementary strand of the incoming DNA is synthesized in the recipient. After transfer, each bacterium contains a copy of the plasmid and can therefore act, in turn, as a donor.

Transposons

Transposons are DNA fragments that can migrate from one replicon to another while retaining their structural integrity (Figure 6). Transposons encode a transposase that allows site-specific insertion and excision. They can transfer actively, in the case of conjugative transposons of Gram-positive cocci, or passively when they are borne by a transferable plasmid. Integrons, as described above, are found frequently as part of transposons, and transposons are frequently carried on plasmids. Numerous plasmids and transposons carry antibiotic resistance genes; often several of them. Furthermore, mobile genetic elements carrying antibiotic resistance genes often encode resistance to heavy metals and detergents. Thus, selection pressure exerted by biocides may select for antibiotic resistance.

As already mentioned, there are two major pathways to antibiotic resistance: mutational events in the chromosome or acquisition of foreign genes.

Mutations can occur not only in a structural gene for the target of an antibiotic (as discussed for quinolones) but also in regulatory regions of genes (for example efflux pumps).

Resistance to an antibiotic is often inducible by the antibiotic itself. In this case, the drug should be considered as having two types of activities; induction of resistance and killing of the bacteria, that act on distinct targets. Acquired resistance to vancomycin is a typical example of inducibility. Expression of the resistance genes of the *van* operon is controlled by a two-component regulatory system VanS/VanR, in which VanS acts as a sensor and VanR as a transcriptional regulator (Figure 2). In the presence of vancomycin in the environment, the signal is transduced from the sensor domain to the catalytic domain of VanS, leading to autophosphorylation of VanS followed by transfer of the phosphoryl group to the VanR response regulator. The phosphorylated regulator binds to the promoter regions resulting in transcriptional activation of the regulatory (*vanR/vanS*) and of the resistance genes, allowing expression of the resistance pathway (synthesis of modified peptidoglycan precursors) and elimination of the normal precursors ending in D-Ala-D-Ala. Under non-inducing conditions, that is in the absence of vancomycin, VanS acts as a phosphatase, dephosphorylates VanR resulting in arrest of expression of the resistance genes. Since antibiotic resistance usually corresponds to a gain of function, there is an associated biological cost resulting in the loss of fitness of the bacterial host. It therefore appears that modulation of gene expression probably reflects a good compromise between energy saving and adaptation to a rapidly changing environment.

Antibiotics Could act as Pheromones

Antibiotics provide selective pressure for resistant bacteria to maintain and disseminate but they can also induce transfer of resistance genes. For example, it has been reported that (i) use of subinhibitory concentrations of penicillins increase the conjugal transfer of plasmid DNA from *E. coli* to *S. aureus* and *L. monocytogenes*, (ii) oxacillin increased the frequency of *in vitro* transfer of Tn916, an enterococcal conjugative transposon, from *E. faecalis* to *Bacillus anthracis*, (iii) transfer frequency of conjugative transposons belonging to the Tn916/Tn1545 family, that contain a tetracycline resistance determinant, is increased 10- to 100-fold *in vitro* and *in vivo* in the presence of low concentrations of tetracycline, and (iiii) tetracycline also increases the transfer of a *Bacteroides* conjugative transposon.

Thus, several antibiotics can behave like pheromones: they are synthesized by specific cells (such as the *Actinomycetes* producers) and they act on another cell, at low concentrations, on very specific targets to promote DNA exchange.

Biological Cost of Antibiotic Resistance

The frequency of appearance of resistant strains in a bacterial population depends on several factors such as the volume of antibiotic use, the biological cost of resistance, and the ability of bacteria to compensate for the fitness cost. Acquisition of antibiotic resistance

Figure 6 Replicative transposition. The donor replicon (lower left) contains a copy of the transposon (close bar; the direction of replication is indicated by an arrow) whereas the acceptor replicon (upper left) does not. Selective replication of the transposon and replicon fusion generate a bireplicon that contains two copies of the element, in the same orientation, at the borders of the replicons. Following recombination between the two copies of the element, after completion of transposition, each replicon contains a copy of the element and can thus, in turn, act as a donor.

is often associated with a biological cost because (i) bacteria acquire a new gene or set of genes responsible for new functions, (ii) the resistance mutations occur in genes with essential functions or (iii) of the replication and maintenance of extrachromosomal elements that bear the resistance genes. The biological cost allows determination of the stability and the potential reversibility of resistance. It can affect the growth rate *in vitro* or the survival in the host or in the environment and can modify the virulence capacity of the strain. Thus, the fitness cost of antibiotic resistance could be assessed by measuring, in isogenic (susceptible and resistant) strains, the growth rate *in vitro* or in animals. A compensatory evolution could occur to reduce the biological cost, allowing the stabilization of the resistant bacteria in a natural population. This stabilization may allow resistant strains to compete with susceptible strains in an antibiotic-free environment. The compensatory evolution could be the result of (i) a true reversion of the resistance mutation or loss of the resistant element or (ii) an acquisition of a second mutation (reverse mutation) located in the same (intragenic) or in another (extragenic) gene. Reversion mutations are more common than reversion to the susceptible phenotype. Once the resistant and compensated mutants are fixed in the bacterial population, a reversion to susceptibility is unlikely. Chances of reversibility of the resistance are also reduced in case of co-resistance to several antibiotics.

It was observed by competition experiments in *Helicobacter pylori* that clarythromycin resistance confers a biological cost in mice. Reduction of this cost, which was observed in clinical isolates, suggests that compensation is a clinically relevant phenomenon.

Comparison of the growth of a fosfomycin sensitive uropathogenic *E. coli* strain with that of an isogenic mutant resistant to this antibiotic obtained *in vitro*, revealed that the growth of the latter is altered in a medium that does not contain fosfomycin.

The biological fitness was also partially or totally restored in fusidic acid resistant mutants of *S. aureus* and *S. typhimurium* and in rifampin resistant mutants of *E. coli*. Similar results were obtained in *S. enterica* that were resistant to a deformylase inhibitor, an antibiotic that targets peptide deformylase. Resistance mutations, that occur in the *fnt* or *folD* gene, confer a fitness cost in the absence of antibiotics. Intragenic mutations in the *fnt/folD* genes or extragenic mutations (such as amplification of genes encoding tRNAi) partially reduce the fitness cost.

Some resistant bacteria could have a normal growth suggesting that they have acquired a no-cost resistance mutation. A specific substitution in the *rpsL* gene (which encodes ribosomal protein S12), responsible for streptomycin resistance in several enteric bacteria, is a typical example of a no-cost high-level resistance mutation.

Regulation of gene expression plays an important role. It has been demonstrated that, in the absence of induction by vancomycin, carriage of the *vanB* locus by the conjugative transposon Tn1549 has no biological cost in *E. faecalis*. However, induced or constitutively resistant strains have a reduced fitness and are impaired in colonization ability and dissemination among mice. Thus, tight regulation of gene expression could be responsible for the modulation of the biological cost and, consequently, of the dissemination of the resistant strains.

Finally, the fitness cost of resistance depends on several factors such as the environmental conditions, the bacterial species, the specific resistance mutation or the growth conditions. The methods used to determine the fitness cost are also crucial: one study demonstrates that no fitness cost was associated with vancomycin resistance in enterococci whereas another group found that vancomycin-susceptible enterococcal strains were more fit than their resistant counterparts.

Conclusion

Intrinsic or acquired resistance to antimicrobial drugs could be the result of different mechanisms. Resistance could (i) be limited to one class of antibiotics or (ii) involve several classes by extended cross-resistance or co-resistance. Resistance determinants that are chromosomally located could be vertically inherited whereas those that are part of mobile genetic elements can be vertically and horizontally acquired. There are three levels of exponential dissemination of antibiotic resistance: epidemics of resistant bacteria among mammals, resistance-plasmid epidemics due to the broad host range of conjugation, and gene epidemics among bacteria (transposons, integrons). Thus, resistance genes can easily disseminate under natural conditions. The biological cost associated with resistance, when it exists, is frequently reduced by a compensatory evolution that allows the stabilization of the resistant bacteria in the population. It is thus necessary to develop (i) strategies to reduce resistance dissemination (such as prudent use of antibiotics, increase of surveillance resistance) and (ii) new antibiotics addressing novel targets and thus escaping to cross-resistance with already developed drug. However, many *in vitro* and *in vivo* studies indicate that several pathways will confer, soon or later, resistance to every new antibiotic.

Glossary

Emerging fungal infections Infections caused by new or uncommon fungi.

Granulocytopenia/neutropenia Acquired or chemically induced immunosuppression caused by low white blood cell counts.

Immunocompromised Having a defect in the immune system.

In vitro and in vivo Describing or referring to studies carried out in the test tube and in animals, respectively.

Mycoses and mycotic infections Diseases caused by yeasts or molds.

Nephrotoxicity Damage to the kidney cells.

Opportunistic infections Infections caused by saprophytic fungi or not true parasites.

Abbreviations

AMB	Amphotericin B
CSF	Cerebrospinal fluid
DMPC	Dimyristoyl phosphatidylcholine
DMPG	Dimyristoyl phosphatidylglycerol
ECV	Epidemiological cutoff values
GVHD	Graft-versus-host disease
HSCT	Hematopoietic stem cell transplant
IS	Isavuconazole, rezafungin (CD101IV), (R) ibrexafungerp (SCY-078), APX001 (E1210)
MEC	Minimal effective concentration
MIC	Minimal inhibitory concentration
NYS	Nystatin
OPC	Oropharyngeal candidiasis

Defining Statement

Antifungal agents are naturally occurring or synthetically produced compounds that have in vitro or in vivo activity against yeasts, molds, or both. Fungi and mammalian cells are eukaryotes, and antifungal agents that inhibit synthesis of proteins, RNA, and DNA are potentially toxic to mammalian cells.

Introduction

Fungi can be unicellular (yeasts) and multicellular or filamentous (molds) microorganisms. Some medically important fungi can exist in both of these morphologic forms and are called dimorphic fungi. Of the estimated 250,000 fungal species described, fewer than 150 are known to be etiologic agents of disease in humans. Most fungi associated with disease are considered opportunistic pathogens (especially the yeasts) because they live as normal flora in humans, lower animals and plants, and rarely cause disease in otherwise healthy individuals. Many fungi, on the contrary, are important plant and lower animal parasites and can cause damage to crops (wheat rust, corn smut, etc.) and to fruit (banana wilt), forest (Dutch elm disease), and ornamental trees and other plants. Historically, the potato famine, which was the reason for the great migration from Ireland to the Americas, was caused by a fungal infection (potato blight). At the same time, fungi and their products play an important economic role in the production of alcohol, certain acids, steroids, antibiotics, and so on.

Because, the number of fungal diseases caused by both yeasts and molds has significantly increased during the past 20 years, especially among immunocompromised patients at high risk for life-threatening mycoses, 15 antifungal agents are currently licensed for the treatment and prevention of systemic fungal infections: the polyene amphotericin B and its three lipid

[☆]Change History: May 2019 A. Espinel-Ingroff updated the text figures and references.

This article is an update of A. Espinel-Ingroff, Antifungal Agents, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 205–222.

formulations, the pyrimidine synthesis inhibitor 5-fluorocytosine (flucytosine), the imidazoles miconazole and ketoconazole, the triazoles fluconazole, isavuconazole, itraconazole, posaconazole, voriconazole, and the echinocandins caspofungin, micafungin, and anidulafungin. However, the number of fungal diseases caused by both yeasts and molds and the continued incidence of resistance and cross-resistance has significantly increased during the past years, especially among the larger number of immunocompromised patients. More recently, *Candida auris* has emerged as a new species causing candidemia infections that appear to be resistant to most available agents. All those factors have prompted the current development of two new echinocandins (Ibrexafungerp [SCY-078] and rezafungin [CD101IV] and the cell wall inhibitor APX001 [E1210]); these three new agents are undergoing Phase II to III clinical trials. There are other agents for topical treatment as well as agriculture and veterinary use, and more importantly, several compounds are under investigation for the management of severe and/or refractory fungal infections in humans. Table 1 only lists the antifungal agents that are useful in the clinical setting or currently under development (Phase II to III clinical trials) or in the veterinary/agriculture world. In addition, a brief description is provided for a variety of compounds with potential clinical use, as well as for those that have been discontinued due to toxicity and other issues.

The Polyenes

The polyenes are macrolide molecules that target membranes containing ergosterol, which is an important sterol in the fungal cell membranes. Traces of ergosterol are also involved in the overall cell cycle of fungi.

Nystatin

Nystatin was the first of the polyenes to be discovered when it was isolated from *Streptomyces noursei* in the early 1950s. It is an amphoteric tetraene macrolide that has a similar structure (Fig. 2A) and identical mechanism of action to those of amphotericin B. Although it has an in vitro spectrum of activity similar to that of amphotericin B, this antifungal is used mostly for the therapy of gastrointestinal (orally) and mucocutaneous candidiasis (topically). This is not only due to its toxicity after parenteral administration to humans and lower animals but also to its lack of effectiveness when given i.v. to experimental animals. It is used for candidiasis in small animals and birds and for otitis caused by *Microsporum canis*.

Amphotericin B

Amphotericin B is the most important of the 200 polyenes. Amphotericin B replaced 2-hydroxystilbamidine in the treatment of blastomycosis in the mid-1960s. Two amphotericins (A and B) were isolated in the 1950s from *Streptomyces nodosus*, an aerobic bacterium, from a soil sample from Venezuela's Orinoco River Valley. Amphotericin B (the most active molecule) has seven conjugated double bonds, an internal ester, a free carboxyl group, and a glycoside side chain with a primary amino group (Fig. 1A). It is unstable to heat, light, and acid pH. The in vitro spectrum of activity of amphotericin B includes yeasts, dimorphic fungi, and most of the opportunistic molds. The fungistatic (inhibition of fungal growth) and fungicidal (lethal or killing) activity of amphotericin B is due to its ability to combine with ergosterol in the cell membranes of susceptible fungi. Pores or channels are formed causing osmotic instability and loss of membrane integrity. This effect extends to mammalian cells. The drug also binds to cholesterol, creating the high toxicity associated with all conventional polyene agents. A second mechanism of antifungal action has been proposed for amphotericin B, which is oxidation-dependent. Amphotericin B is highly protein bound (91–95%). Peak serum of 1–3 $\mu\text{g mL}^{-1}$ and trough concentrations of 0.5–1.1 $\mu\text{g mL}^{-1}$ are usually measured after the intravenous (i.v.) administration of 0.6 mg/kg doses. Its half-life of elimination is 24–48 h, with a long terminal half-life of up to 15 days.

Since amphotericin B is insoluble in water, aqueous solubility of amphotericin B is achieved by formulation with deoxycholate resulting in the amphotericin B deoxycholate clinical formulation; the variety of lipid formulations will be discussed below. Although amphotericin B penetrates poorly into the cerebrospinal fluid (CSF), amphotericin B is effective in the treatment of invasive *Aspergillus*, *Candida* (alternative therapy), *Mucorales* and *Cryptococcus meningitis* (alone and/or in combination with 5-fluorocytosine for the latter infections) as well as other mold infections (Table 1). Toxicity is the limiting factor during amphotericin B therapy and has been classified as acute or delayed (Table 2). Nephrotoxicity is the most significant delayed adverse effect and initial therapy is not recommended with this drug when the patient is at high nephrotoxicity risk. Therefore, close monitoring of renal function tests, bicarbonate, electrolytes including magnesium, diuresis, and hydration status is recommended during amphotericin B therapy. Current recommendations regarding daily dosage, total dosage, duration, and its use in combination with other antifungal agents are based on the type of infection and the status of the host (Pappas et al., 2016; Perfect et al., 2010; Patterson et al., 2016). Because severe fungal infections in the granulocytopenic host are difficult to diagnose and cause much mortality, empirical antifungal therapy with amphotericin B and other agents has improved patient care. Systemic prophylaxis for patients at high risk for invasive mycoses has also evolved. Amphotericin B adverse drug interactions can occur with the administration of electrolytes and other concomitant drugs. This drug is also used in these animals for the treatment of systemic infections (e.g., blastomycosis in dogs), but it is not effective against aspergillosis. Side effects (especially in cats) and drug interactions are similar to those in humans.

Table 1 Antifungal agents, mechanisms of action, and their use.

Antifungal class	Antifungal target of action	Agent	Use
Polyenes	Membranes containing ergosterol	Amphotericin B (AMB)	Systemic mycoses ^{a,b}
		Nystatin (NYS)	Superficial mycoses ^{a,b}
		AMB lipid formulations: Ambisome Abelcet	Alternative use for invasive mycoses (candidiasis and aspergillosis included) refractory and/or in patients intolerant to conventional AMB (for other specific indications, see below).
		Amphocet	
		Ambisome, Liposomal AMB, LAMB	Empirical, febrile neutropenic patients; cryptococcal meningitis in AIDS patients; prophylaxis in liver transplant patients; severe disseminated histoplasmosis
		Abelcet, AMB lipid complex, ABLC	See above
		Amphotec, AMB colloidal dispersion, ABCD	See above
		Pimaricin	Topical keratitis ^a
Phenolic cyclohexane	Microtubule aggregation and DNA inhibition	Griseofulvin	Dermatophytic infections ^a
Natural glutarimide	Protein synthesis inhibition	Cycloheximide	Laboratory and agriculture
Phenylpyrroles	Unknown	Fenpiclonil	Agriculture
Synthetic pyrimidines	Fungal cytosine permease and deaminase	Flucytosine	In combination with AMB, cryptococcal meningitis in HIV patients ^a
	Ergosterol inhibition	Triarimol	Agriculture
Azoles	Ergosterol biosynthesis inhibition	<i>Imidazoles</i>	
		Clotrimazole	Topical, oral troche ^{a,b}
		Econazole	Skin infections (ring worm, Athlet's foot, tinea versicolor, etc.)
		Isoconazole	Topical infections
		Oxiconazole	Skin infections (ring worm, Athlet's foot, etc.)
		Tioconazole	Ointment for vaginal yeast infections
		Fenticonazole	Mixed <i>Candida</i> and bacterial infections.
		Miconazole	Topical and veterinary ^b
		Ketoconazole	Second-line drug for nonmeningeal systemic mycoses and veterinary ^{a,b}
		Enilconazole	Veterinary
		Epoxiconazole	Agriculture (pesticide)
		Fluquinconazole	
		Triticonazole	
		Prochoraz	
		<i>Triazoles</i>	
		Fluconazole	Candidiasis, cryptococcosis, coccidioimycosis, prophylaxis ^b
		Itraconazole	Candidiasis, aspergillosis, endemic mycoses, superficial diseases, long-term prophylaxis ^a
		Posaconazole	Prophylaxis (invasive <i>Aspergillus</i> and <i>Candida</i> infections), oropharyngeal candidiasis (OPC)
		Voriconazole	<i>Aspergillus</i> and <i>Candida</i> infections, salvage therapy (<i>S. apiospermum</i> and <i>Fusarium</i> infections) ^a
Allylamines Benzylamines Thiocarbamates		Terbinafine	Superficial infections
		Butenafine	Topical
		Tolnaftate	Topical
Dithiocarbamates	Nonspecific	Mancozeb	Agriculture
		Thiram	
Benzimidazoles and methylbenzimidazole carbamates	Nuclear division	Carbendazim	Pesticide
		Benomyl Thiophanate	

Table 1 Continued

Antifungal class	Antifungal target of action	Agent	Use
Morpholines	Ergosterol biosynthesis inhibition	Amorolfine	Topical
		Fenpropimorph	Agriculture
		Tridemorph	Pesticide
Pyridines		Buthiobate	Agriculture
		Pyrifeno	Pesticide
Echinocandins	Fungal (1,3)-glucan synthase inhibition	Anidulafungin	Invasive <i>Candida</i> infections, including candidemia, esophageal candidiasis ^a
		Caspofungin	Invasive <i>Candida</i> infections, including candidemia; empirical therapy (febrile neutropenic patients unresponsive to antibacterial therapy); salvage therapy (aspergillosis) ^a
		Micafungin	Invasive <i>Candida</i> infections including candidemia and esophageal candidiasis in adult patients. Prophylaxis for HSCT patients and liver transplants ^a
Under development		Ibrexafungerp (SCY-078)	<i>Candida</i> and <i>Aspergillus</i> infections: Phases II to III clinical trials for vaginal infections, invasive candidiasis and aspergillosis (oral formulation). IV formulation under development.
Under development		Rezafungin (CD101 IV)	<i>Candida</i> , <i>Aspergillus</i> , and <i>Pneumocystis</i> infections: Phase II to III clinical trials for invasive candidiasis, including candidemia, and prophylaxis of fungal infections (IV formulation).
Other fungal cell wall inhibitor: Under development	Glycosylphosphatidylinositol biosynthesis inhibition	APX001 (E1210)	<i>Candida</i> , <i>Aspergillus</i> , <i>Fusarium</i> and other mold infections. Phase I to II clinical trials of murine disseminated candidiasis (including oral infections), pulmonary aspergillosis and fusariosis.
Cinnamic acid	Cell wall	Dimethomorph	Agriculture
Oomycete fungicide	Oxidative phosphorylation	Fluazynam	Agriculture
Phthalimides	Nonspecific	Captan	Agriculture, horses (dermatophytic infections)

Only licensed, commonly used, and antifungals under clinical investigation are listed; see older versions of this review for other antifungal agents.

^aClinical and veterinary use; other applications for use in humans only.

^bA human product used in veterinary.

Although resistance to amphotericin B is rare, both in vitro and in vivo resistance has been reported. Information regarding the mechanisms of amphotericin B resistance is mostly available for *Candida albicans*, *Aspergillus terreus*, and *A. flavus*. Alterations of the fungal cell wall composition, a lower ergosterol content and a higher catalase production have been reported to be responsible for in vitro resistant in *A. flavus* and *A. terreus*. Clinically, resistance to amphotericin B has become an important problem, particularly with certain yeast and mold species for which high MICs (minimal inhibitory concentrations) are usually obtained, such as *Candida lusitanae* (*Clavispora lusitanae*), *A. terreus* (poor response to different formulations of amphotericin BMICs >1 µg/mL), *Fusarium* spp., *Malassezia furfur*, *Scedosporium apiospermum* complex (*Pseudallescheria boydii*), *Lomentospora* [*Scedosporium*] *prolificans*, *Trichosporon beigelii*, and other emerging fungal pathogens, such as *C. auris* (30–40% resistance) (Clancy and Nguyen, 2017). Although clinical breakpoints are not available for any fungal species and amphotericin B, species-specific epidemiological cutoff values (ECVs) have been defined for the more prevalent *Candida* spp., *Aspergillus* spp., and the *Cryptococcus neoformans*-*C. gattii* complex (Espinel-Ingroff and Turnidge, 2016; CLSI M59 document, 2018). These ECVs will distinguish wild-type (WT, isolates without mechanisms of resistance) from non-WT isolates (mutants or isolates with known mechanisms of resistance and potential reduced susceptibility to the agent being evaluated). In addition, amphotericin B MICs >0.5 and > 1 µg/mL are found in the literature as default cutoffs for resistance or nonsusceptibility to this drug and its lipid formulations, but this cutoff is mostly based on obtaining peak serum concentrations of 2 µg/mL. However, correlations of in vivo versus in vitro results using the available MIC methodology have not been established, but MICs above 2 µg/mL for *Aspergillus* spp. (or above the ECV) have been associated with treatment failures and MICs below 2 µg/mL with clinical cure.

Amphotericin B liposomal, lipid complex and colloidal formulations

With the outcome of azole resistance associated with treatment failure, amphotericin B lipid formulations have become useful alternatives for the treatment of invasive azole-resistance aspergillosis and candidiasis (Pappas et al., 2016; Patterson et al., 2016). The three lipid formulations of amphotericin B are indicated in the treatment of invasive fungal infections (candidiasis and aspergillosis included) caused by susceptible fungal pathogens that are refractory to/or in patients intolerant to conventional

agent are: (i) liposomal amphotericin B (3–5 mg/kg q.d. approved dose, LAMB, *ambisome*); (ii) amphotericin B lipid complex (5 mg/kg q.d. approved dose; ABLC, *abelcet*); and amphotericin B colloidal dispersion (3–4 mg/kg q.d. approved dose, ABCD, *amphotec*). Other specific indications are as follows: (i) *ambisome*, for cryptococcal meningitis in AIDS patients (6 mg/kg q.d. approved dosage), empirical treatment in febrile neutropenic patients with persistent fever despite antibacterial treatment for 5–7 days (approved dose: 3 mg/kg q.d.), disseminated histoplasmosis and prophylaxis in liver transplant patients at risk of fungal systemic infections; (ii) *amphotec*, for invasive aspergillosis in patients with renal impairment, unacceptable toxicity that precludes the use of amphotericin B deoxycholate in effective doses. A brief description of these three agents and other less used lipid formulations can be found below.

In general, these preparations have selective toxicity or affinity for fungal cell membranes and promote the delivery of the drug to the site of infection while avoiding the toxicity of supramaximal doses of conventional amphotericin B. The result is a reduction of human erythrocytes lysis and higher doses of amphotericin B can be safely used. Although most of these formulations have been approved for the treatment of invasive fungal infections, not enough information is available regarding their pharmacokinetics, drug interactions, long-term toxicities, and the differences in both efficacy and tolerance among the three formulations.

Ambisome: liposomal amphotericin B

Ambisome (LAMB; Gilead Sciences, UK [marketed in Europe], Astellas Pharma, formerly Fujisawa Pharmaceuticals [marketed in USA], Sumitomo Pharmaceuticals [marketed in Japan and Australia] is perhaps the most widely used amphotericin B lipid preparation. In this formulation, amphotericin B is incorporated into small unilamellar, spherical vesicles (60- to 70-nm liposomes) in a 2: 0.8:1: 0.4 M ratio. Ambisome is also recommended for the treatment of visceral leishmaniasis.

Abelcet: amphotericin B lipid complex

Abelcet (ABLC, Sigma-Tau Pharmaceuticals) is a preparation of amphotericin B and two phospholipids (DMPC/ DMPG) in a 1:1 drug-to-lipid molar ratio.

Amphotec: amphotericin B colloidal dispersion

Amphotec (ABCD, Ben Venue Laboratories and InterMune, Inc. [manufacturer and distributor, respectively], USA) is a colloidal complex of amphotericin B and cholesteryl sulfate in a 1:1 M ratio.

Amphocil

Amphocil (Samaritan Pharmaceuticals, UK) is another disk shaped colloidal complex of amphotericin B where the drug is also stabilized with cholesteryl sulfate.

Fungisome

Fungisome is the latest and cheapest addition to the lipid formulations of amphotericin B. It is marketed in India by Lifecare Innovations.

Pimaricin (Natamycin)

Pimaricin is a tetraene polyene produced by *Streptomyces natalensis*. It has a higher binding specificity for cholesterol than for ergosterol and, therefore, it is highly toxic for mammalian cells. The therapeutic use of pimaricin is limited to the topical treatment of keratitis (eye infections; also in horses) caused by *Fusarium* spp., *Acremonium* spp., and other mold species.

Phenolic Cyclohexane: Griseofulvin

Griseofulvin is a phenolic, benzyfuran cyclohexane agent (Fig. 2B) that binds to RNA. It is a product of *Penicillium janczewskii* and was the first antifungal agent to be developed as a systemic plant protectant. It acts as a potent inhibitor of thymidylate synthetase and interferes with the synthesis of DNA. It also inhibits microtubule formation and the synthesis of apical hyphal cell wall material. With the advent of terbinafine and itraconazole, the clinical use of griseofulvin as an oral agent for treatment of dermatophytic infections has become limited. However, it is frequently used for these infections in small animals, horses, and calves (skin only) as well as for equine sporotrichosis. Abdominal adverse side effects have been noted, especially in cats.

Natural Glutarimide: Cycloheximide

This is a glutaramide agent produced by *S. griseus*. This agent was among the three antifungal agents reported between 1944 and 1947. Although cycloheximide had clinical use in the past, it is currently used as a plant fungicide and in the preparation of laboratory media.

Phenylpyrroles: Fenpiclonil

Although this agent is used in agriculture, the mechanism of action is unknown.

The Synthetic Pyrimidines**5-Fluorocytosine (Flucytosine)**

The synthetic 5-fluorocytosine has only fungistatic activity against yeasts and some dermatophytes. It is an oral, low-molecular-weight, fluorinated pyrimidine related to 5-fluorouracil and floxuridine (Fig. 1B). It acts as a competitive antimetabolite for uracil in the synthesis of yeast RNA. Two enzymes are involved in the mode of action of 5-fluorocytosine: a membrane-bound *permease* (drug uptake) and a *deaminase* (conversion to the main active form, 5-fluorouracil). Flucytosine resistance may arise from a mutation of an enzyme necessary for the cellular uptake or metabolism of the drug or from an increased synthesis of pyrimidines, which compete with the drug metabolites, e.g., mutations in the *FCY2*, *FCY1*, and *FUR1* genes encoding cytosine permease, cytosine deaminase, and uracil phosphoribosyltransferase, respectively (Table 4). Resistance to flucytosine has been shown to emerge after monotherapy and prolonged exposure to the drug. *C. krusei* should be considered to be resistant to flucytosine. Although clinical breakpoints and ECVs are not available for *Candida* spp., ECVs have been approved for the *C. neoformans*-*C. gattii* complex (Espinel-Ingroff and Turnidge, 2016; CLSI M59 document, 2018).

Clinically, the major therapeutic role of 5-fluorocytosine is its use in combination with amphotericin B in the treatment of meningitis caused by *C. neoformans*-*C. gattii* complex in AIDS patients (Table 1; Perfect et al., 2010). 5-Fluorocytosine should not be used alone for the treatment of any fungal infections. The most serious toxicity associated with 5-fluorocytosine therapy is bone marrow suppression (6% of patients), which leads to neutropenia, thrombocytopenia, or pancytopenia (Table 2). Therefore, monitoring of the drug concentration in the patient's serum (serial 2-h levels post-oral administration) is highly recommended to adjust dosage and maintain serum levels between 40 and 60 g mL⁻¹. Because the drug is administered in combination with amphotericin B, a decrease in glomerular filtration rate, a side effect of the latter compound, can induce increased toxicity to 5-fluorocytosine. Adverse drug interactions can occur with other antimicrobial and anticancer drugs, cyclosporine, and other therapeutic agents. Given its toxic potential, 5-fluorocytosine should not be administered to pregnant women or animals. This drug has been used in combination with ketoconazole for cryptococcosis in small animals (very toxic for cats) and also for respiratory aspergillosis and severe candidiasis in birds.

Triarimol, Fenarimol, Pyrimethanil, and Cyprodinil

Triarimol and fenarimol are pyrimidines that inhibit lanosterol demethylase, an enzyme involved in the synthesis of ergosterol, while the anilinoimidazoles, pyrimethanil and cyprodinil, inhibit the secretion of the fungal enzymes that cause plant cell lysis, which leads to the inhibition of this biosynthesis pathway. However, the activity is lost after several applications. Only Triarimol is used in agriculture in some countries.

The Azoles

The azoles are the largest single source of synthetic antifungal agents; the first azole was discovered in 1944. As a group, they are broad spectrum in nature and mostly fungistatic. The broad spectrum of activity involves fungi (yeasts and molds), bacteria, and parasites. This group includes fused ring and N-substituted imidazoles and the N-substituted triazoles. The mode of action of these compounds is the inhibition of lanosterol demethylase, a cytochrome P450 enzyme.

Fused-Ring Imidazoles (Flubendazole)

The basic imidazole structure is a cyclic five-member ring containing three carbon and two nitrogen molecules. In the fused-ring imidazoles, two carbon molecules are shared in common with a fused benzene ring. Most of these compounds have parasitic activity (anthelmintic); two have limited antifungal activity: 1-chlorobenzyl-2-methylbenzimidazole and thiabendazole (previously used for superficial yeast and dermatophyte infections and aspergillosis and penicilliosis in dogs, respectively).

Recently, the amorphous solid compound flubendazole is a benzimidazole (Janssen Pharmaceutica) that was developed for the oral treatment of some tropical diseases, including onchocerciasis. It also has in vitro activity (low MICs) against *C. neoformans* by binding to cryptococcal β -tubulin. Although flubendazole showed oral bioavailability in rabbits, there was no quantifiable drug concentrations or antifungal activity in either the CSF or cerebrum. These results indicated that for flubendazole to be useful for cryptococcal meningitis treatment, further studies are needed to increase the drug gut absorption and the optimal drug levels into the different CNS areas (Nixon et al., 2018).

N-Substituted (Mono) Imidazoles

In this group, the imidazole ring is intact and substitutions are made at one of the two nitrogen molecules. At least three series of such compounds have emerged for clinical and agricultural use. In the triphenylmethane series, substitutions are made at the nonsymmetrical carbon atom attached to one nitrogen molecule of the imidazole ring. In the second series, the substitutions are made at a phenethyl configuration attached to the nitrogen molecule. The dioxolane series is based on a 1,3-dioxolane molecule rather than on the 1-phenethyl molecule. These series vary in spectrum, specific level of antifungal activity, routes of administration, and potential uses.

Clotrimazole

Clotrimazole is the first member of the triphenylmethane series of clinical importance (Table 1; Fig. 2C). It has good in vitro activity at very low concentrations against a large variety of fungi (yeasts and molds). However, hepatic enzymatic inactivation of this compound, after systemic administration, has limited its use to topical applications (1% cream, lotion, solution, tincture, and vaginal cream) for superficial mycoses (nail, scalp, and skin infections) caused by the dermatophytes and *M. furfur*, for initial and/or mild oropharyngeal candidiasis (OPC; 10-mg oral troche), and for the intravaginal therapy (single application of 500-mg intravaginal tablet) of vulvovaginal candidiasis. Other intravaginal drugs require 3 to 7-day applications. This drug is also used for candidal stomatitis, dermatophytic infections, and nasal aspergillosis (infused through tubes) in dogs.

Econazole, isoconazole, oxiconazole, tioconazole, and fenticonazole

Other frequently used topical imidazoles include econazole (1% cream), isoconazole (1% cream), oxiconazole (1% cream and lotion), and tioconazole (6.5% vaginal ointment) (Table 1). As with clotrimazole, a single application of tioconazole is effective in

the management of vulvovaginal candidiasis and as a nail lacquer for fungal onychomycosis (nail infections). Mild to moderate vulvovaginal burning has been associated with intravaginal therapy. Oxiconazole and econazole are less effective than terbinafine and itraconazole in the treatment of onychomycosis and other infections caused by the dermatophytes. Although topical agents do not cure onychomycosis as oral drugs do, they may slow down the spread of this infection. However, the recommended drugs for the treatment of onychomycosis are terbinafine (by dermatophytes) and itraconazole.

On the other hand, fenticonazole was synthesized and developed in Italy in the 1990s and has been used for the topical treatment of infections caused by dermatophytes and especially for *Candida* vaginitis. Recently, based on an in vitro study, the use of this agent was recommended for the treatment of vaginal infections caused by a combination of *Candida* and bacteria agents or with different etiology in order to minimize the possibility of antimicrobial resistance (Sanguinetti et al., 2019).

Miconazole

Miconazole (Fig. 1C) was the first azole derivative to be administered intravenously for the therapy of systemic fungal infections. Clinically is only used as a topical agent for dermatophytic infections in humans and other large animals, fungal keratitis and pneumonia in horses, in birds, and aspergillosis in raptors. However, safety and efficacy data are not available (veterinary use). It is also available as vaginal suppository.

Ketoconazole

Ketoconazole was the first representative of the dioxolane series (Table 1; Fig. 1D) to be introduced into clinical use and was the first orally (tablet) active azole. This drug has a broad spectrum of in vitro activity, but due its adverse side effects, drug interactions and the high rate of relapses, it been replaced by itraconazole and other triazoles in most countries. However, creams (for *tinea*, *cutaneous candidiasis*, and *pityriasis versicolor*) and shampoos (for dandruff or *seborrhoeic dermatitis* of the scalp) are available. Therapeutic failure with ketoconazole has been associated with low serum levels; monitoring of these levels is recommended in such failures. Ketoconazole also has been used for a variety of systemic and superficial fungal infections in cats and dogs. Ketoconazole requires a normal intragastric pH for absorption, for example an increase in pH will decrease its absorption in patients with gastric achlorhydria or treated with antacids or H₂-receptor antagonists (Table 3). This drug should be taken with either orange juice or a carbonated beverage. Ketoconazole pharmacokinetics corresponds to a dual model with an initial half-life of 1–4 h and a terminal half-life of 6–10 h, depending on the dose. This drug highly binds to plasma proteins and penetrates poorly into the CSF, urine, and saliva. Peak plasma concentrations of approximately 2, 8, and 20 µg mL⁻¹ are measured 1–4 h after corresponding oral doses of 200, 400, and 800 mg. The most common and dose-dependent adverse effects are nausea, anorexia, and vomiting in 10% of the patients receiving a 400 mg dose and in approximately 50% of the patients taking 800 mg or higher doses (Table 2).

Table 3 Adverse interactions of the licensed systemic antifungal agent with other drugs during concomitant therapy.

Azole	Concomitant drug	Adverse side effect of interaction
V		Non-melanoma skin cancer
K, FL, I	Nonsedating antihistamines, cispripide, terfenadine, astemizole	Fetal arrhythmia
K, FL, I, V, C	Rifampin, isoniazid, phenobarbital, rifabutin, carbamazepine, and phenytoin	Reduces azole or C plasma concentrations
K, FL, I, V	Phenytoin, benzodiazepines, rifampin	Induces the potential toxicity levels of co-compounds
K, I	Antacids, H ₂ antagonists, omeprazole, sucralfate, didanosine	Reduces azole absorption
K, FL, I	Lovastatin, simvastatin	Rhabdomyolysis
I	Indinavir, vincristine, quinidine, dicyclosporine, tacrolimus, methylprednisolone, and ritonavir	Induces potential toxicity co-comogoxin, compounds
FL, I, V	Warfarin, rifabutin, sulfonyleurea	Induces potential toxicity of co-compound
K	Saquinavir, chlordinazepoxide, methylprednisone	Induces potential toxicity of these compounds
K	Protein-binding drugs	Increases the release of fractions of free drug
K, C, V	Cyclosporine A	Nephrotoxicity
C, V	Tacrolimus	Tacrolimus can be decreased
C	Efavirenz, nevirapine, phenytoin, dexamethasone	C can be reduced (70 mg of C should be considered)
V	Omeprazole	Reduces omeprazole dose to one half
P	Phenytoin, cimetidine	Reduces P exposure
		Induces C clearance
P	Cyclosporine A, tacrolimus	Increases concomitant drug exposure
C	Carbamazepine, rifampin, dexamethason	Induces C clearance
P	Midazolam	
P	Rifabutin	Two-way interactions
M	Sirolimus, nifedipine or itraconazole	Increases concomitant drug exposure

K, ketoconazole; FL, fluconazole; I, itraconazole; P, posaconazole; V, voriconazole; C, caspofungin.

See Clinical pharmacology of systematic antifungal agents: *Advances in Pharmacology* and the NIH website for antifungal drugs.

Table 4 Reported molecular mechanisms of resistance for the most important systemic antifungal agents.

Antifungal agent and molecular mechanism	Resulting effect
Azoles and <i>Candida</i> spp.: CDR1/CDR2 and MDR1 upregulation due to point mutations in TAC1 and MRR1 transcription factors	Upregulation of drug transporters
Gene (<i>ERG11</i>) point mutations	Decreased lanosterol 14- α -demethylase binding affinity for the drug
<i>ERG11</i> upregulation due to gene duplication and transcription factor regulation	Increased concentration of lanosterol 14- α -demethylase
Gene (<i>ERG3</i>) point mutations	Inactivation of C5 sterol desaturase leading to alterations in the synthetic pathway
Azoles and <i>Aspergillus</i> spp.: Gene (<i>cyp51</i>) single or multiple point mutations	Increased level of gene expression
Echinocandins: Gene point mutations (FKS1 and FKS2)	Decreased glucan synthase or drug affinity
Polyenes: Gene (<i>ERG3</i> and <i>ERG6</i>) point mutations	Decreased cell ergosterol content
Flucytosine and other nucleoside analogs	
Gene (<i>FCY2</i>) point mutations	Inactivation of cytosine permease affecting drug uptake
Gene (<i>FCY1</i>) point mutations	Inactivation of cytosine deaminase leading to alterations in 5-fluorocytosine metabolism
Gene (<i>FUR1</i>) point mutations	Inactivation of uracil phosphoribosyl transferase leading to alterations in the metabolism of 5-fluorocytosine

Enilconazole

This is the azole most widely used in veterinary practice for the intranasal treatment of aspergillosis and penicilliosis as well as for dermatophytic infections. The side effects are few.

Epoxiconazole, fluquinconazole, triticonazole, and prochloraz

Epoxiconazole, fluquinconazole, and triticonazole are important agricultural fungicides, which have a wider spectrum of activity than that of the earlier triazoles, triadimefon, and propiconazole, and the imidazole, prochloraz, as systemic cereal fungicides. However, development of resistance to these compounds has been documented.

The Triazoles

The triazoles are characterized by a more specific binding to fungal cell cytochromes than to mammalian cells due to the substitution of the imidazole ring by the triazole ring. Other beneficial effects of this substitution are (1) an improved resistance to metabolic degradation, (2) an increased potency, and (3) a superior antifungal activity. Several triazoles, including isavuconazole, are licensed for antifungal systemic therapy (Table 1) and others are under clinical investigation.

Triazole resistance, molecular resistance mechanisms

The wide use of fluconazole and other triazoles led to in vitro resistance among *Candida* and other yeast isolates (See below for listing of some species). The molecular mechanisms associated with in vitro resistance to the triazoles among *Candida* spp. are: (i) modifications in the quality or quantity of the target enzyme, reduced access of the drug to the target, mutations in the *ERG* genes participating in ergosterol biosynthesis, or a combination of these mechanisms, and (ii) an active efflux of azole out of the cell through the activation of multidrug efflux transporters encoded by the *MDR* and *CDR* genes; these mechanisms have been linked to in vitro and clinical resistance. On the other hand, acquired azole resistance among *Aspergillus* spp. (mostly investigated in *A. fumigatus* and *A. flavus*) is associated with single or multiple point mutations of the *CYP51* gene that encodes the enzymes 14- α -sterol demethylases A and B (Table 4; Espinel-Ingroff et al., 2018). These mutations have been linked with multiazole resistance or cross-resistance (high MICs) as well as patient failure during triazole treatment. Not much genetic information is available for other *Aspergillus* spp.

Reduced susceptibility to fluconazole and other triazoles has been widely reported for *Candida non-albicans*, such as *C. glabrata* (>15% resistant), *C. krusei* (intrinsically resistant to fluconazole), *C. lusitanae*; triazole use for the treatment of such infections is precluded. *C. auris* has been recently reported as the cause of candidemia hospital outbreaks in various countries among neonates, elderly or patients having known risk factors for invasive candidiasis. The majority of *C. auris* isolates are fluconazole resistant or resistant to other agents (Clancy and Nguyen, 2017). Resistance and cross-resistance also has increased among *Aspergillus* spp., especially in Europe. Overall, antifungal susceptibility testing is recommended since species-specific clinical breakpoints are now available for fluconazole and voriconazole (but not for posaconazole, itraconazole, or isavuconazole) and most common *Candida* spp., but not for *C. glabrata* (CLSI document M60, 2017). Susceptibility testing should be also performed when the patient is failing therapy to rule out that is due to in vitro resistance. In the absence of clinical breakpoints, CLSI ECVs have been defined for *Aspergillus* spp. versus itraconazole, isavuconazole, posaconazole and voriconazole, some *Candida* spp. and the *C. neoformans*-*C. gattii* complex (Espinel-Ingroff and Turnidge, 2016; CLSI document M59). However, for the first time, the CLSI has recently

proposed breakpoints for *A. fumigatus* and voriconazole as follows: Susceptible: $<0.5 \mu\text{g/mL}$; intermediate: $1 \mu\text{g/mL}$; and resistant: $\geq 2 \mu\text{g/mL}$ (CLSI Annual meeting minutes, January, 2019). The EUCAST has also established both ECVs and breakpoints for a variety of species/drug combinations (http://www.eucast.org/ast_of_fungi/). Although ECVs will distinguish WT from non-WT or mutant isolates when clinical breakpoints are not available, but should not be used when breakpoints are available for the drug/species combination being evaluated. More recently, ECVs have been defined for the widely used SYO commercial method for *S. cerevisiae* and 9 *Candida* spp. including prevalent (*C. parapsilosis* sensu stricto) and less prevalent species (*C. dubliniensis*, *C. guilliermondii*, *C. orthopsilosis*) and *S. cerevisiae* (Espinel-Ingroff et al., 2019). The posaconazole SYO ECV of $0.06 \mu\text{g/mL}$ for *C. albicans* and the Etest itraconazole. ECV of $2 \mu\text{g/mL}$ were the best predictors of non-wild type (mutant) isolates by this commercial method (Espinel-Ingroff et al., 2019).

Fluconazole

Fluconazole is a relatively small molecule (Fig. 1E) that is partially water soluble, minimally protein bound, and excreted largely as an active drug in the urine. It penetrates well into the CSF and parenchyma of the brain and the eye, and it has a prolonged half-life (up to 25 h in humans). Fluconazole pharmacokinetics are linear and independent on the route of administration and the drug formulation. This drug is well absorbed orally (its total bioavailability exceeds 90%), and its absorption is not affected by food or gastric pH. Plasma concentrations of $2\text{--}7 \mu\text{g mL}^{-1}$ are usually measured in healthy subjects after single doses of 100 and 400 mg. After multiple doses, the peak plasma levels are 2.5 times higher than those of single doses. The CSF to serum fluconazole concentrations are between 0.5 and 0.9% in both healthy human subjects and laboratory animals.

Fluconazole does not have in vitro or in vivo activity against most molds. Both oral and i.v. formulations of fluconazole are available for the treatment of candidemia in nonneutropenic and other nonimmunosuppressed patients, mucosal candidiasis (oral, vaginal, and esophageal), and chronic mucocutaneous candidiasis in patients of all ages (Pappas et al., 2016). Fluconazole is the current drug of choice for maintenance therapy of AIDS-associated cryptococcal and coccidioidal meningitis (Table 1; Perfect et al., 2010). However, since resistance to this drug can develop during therapy, fluconazole prophylaxis should be reserved for HIV-infected individuals or AIDS patients, or for patients with prolonged (2 weeks) and profound neutropenia (500 cells). Although the recommended dosage of fluconazole for adults is 100–400 mg each day (q.d.) higher doses (800 mg q.d.) are required for the treatment of severe invasive infections and for infections caused by a *Candida* spp. that exhibit a MIC of $8 \mu\text{g mL}^{-1}$.

Intraconazole

In contrast to the imidazoles and itraconazole, fluconazole does not exhibit major toxicity side effects (2.8–16%). However, when the dosage is increased above 1200 mg, adverse side effects are more frequent (Table 2). Fluconazole interactions with other concomitant drugs are similar to those reported with other azoles, but they are less frequent than those exhibited by ketoconazole and itraconazole (Table 3). Fluconazole has been used to treat nasal aspergillosis and penicilliosis in small animals and birds when topical enilconazole is not feasible.

In contrast to fluconazole, itraconazole is insoluble in aqueous fluids; it penetrates poorly into the CSF and urine but well into skin and soft tissues; and it is highly protein bound (90%). Its structure is closely related to that of ketoconazole (Fig. 1F), but itraconazole has a broader spectrum of in vitro and in vivo antifungal activity. Similar to ketoconazole, itraconazole is soluble only at low pH and is better absorbed when the patient is not fasting. Absorption is erratic in cancer patients or when the patient is taking concomitant H_2 -receptor antagonists. Plasma peak (1.5–4 h) and trough concentrations between $1\text{ and }2.2 \mu\text{g mL}^{-1}$ and $0.4\text{ and }1.8 \mu\text{g}$ dosages (per orally, p.o.) or twice daily (b.i.d.) or after i.v. administration (b.i.d.) for 2 days and q.d. for more days; these concentrations are also obtained in cancer patients receiving 5 mg kg^{-1} .

Clinically, itraconazole (200–400 mg/day, capsule) is indicated for endemic, non-life-threatening mycoses and as a prophylactic agent (Table 1); it is one the agents used for the treatment of sporotrichosis infections. For more severe mycoses (invasive yeast and mold infections), higher doses are recommended and clinical resistance may emerge. Monitoring of itraconazole plasma concentrations is recommended during treatment, drug concentration $0.5 \mu\text{g mL}^{-1}$ by high performance liquid chromatography and $2 \mu\text{g mL}^{-1}$ by bioassay appear to be critical for favorable clinical response (Pappas et al., 2016; Perfect et al., 2010). In summary, a lower trough concentration of 0.25 mg/L (prophylaxis target) or 0.5 mg/L (treatment target) could be the lower effective limits. On the other hand, trough of 1.0 mg/L is associated with increased hepatotoxicity and other adverse events.

But, both i.v. and oral solution formulations have improved its solubility and enhance drug absorption and bioavailability (consistent plasma concentrations) versus capsule formulation. The additional flexibility offered by the different routes of administration means that itraconazole treatment can be used in all patient populations, including children and those requiring intensive care. The oral solution is useful for the treatment of HIV-associated oral and esophageal candidiasis. Treatment with itraconazole has been associated with 10% adverse and mostly transient side effects (Table 2), and these effects are usually observed when the patient takes up to 400 mg during several periods of time.

In animals, itraconazole has prescribed for the treatment of aspergillosis, cryptococcosis, blastomycosis (especially in dogs), equine sporotrichosis, and osteomyelitis caused by *Coccidioides immitis* in large animals, but its use is minimal. No data are available regarding its side effects or drug interactions in animals.

Itraconazole in combination with Pulmazole™ (PUR1900)

Recently, Pulmazole™ (PUR1900) is an inhaled dry powder and oral itraconazole combination that was evaluated in an immunocompromised guinea-pig model of aspergillosis. The animals received either placebo, or PUR1900, or oral itraconazole.

After 10 days of treatment, which began the day after the animals were infected, the drug exposure and animal survival were better among the animals treated with PUR1900 than those treated only with oral itraconazole. So this combined therapy is promising for the treatment of pulmonary aspergillosis and perhaps more advantageous than oral itraconazole (Curran et al, 2018; Advances Against Aspergillosis, Lisbon, Portugal).

Voriconazole (UK-109496)

Voriconazole is a triazole related to fluconazole obtained by replacement of one triazole moiety by fluoropyrimidine and α -methylation groups (Fig. 3A); it is insoluble in aqueous fluids. As do the other azoles, voriconazole acts by inhibiting fungal cytochrome P450-dependent, 14- α -sterol demethylase-mediated synthesis of ergosterol. Voriconazole pharmacokinetics in humans are nonlinear and dose dependent. Following single oral doses, peak plasma concentrations were achieved after 2 h and multiple doses resulted in a higher (eight times) accumulation. The mean half-life of elimination is about 6 h. Voriconazole binds to proteins (65%), is extensively metabolized in the liver (80%), and is found in the urine (78–88%) practically unchanged after a single dose. Voriconazole has good oral bioavailability, distributes widely into tissues including those of the central nervous system. It does not have activity against the Mucorales, certain isolates of *Candida rugosa*, *Sporothrix schenckii* and a significant number of *Rhodotorula* strains, especially *R. muciliginosa*. Clinically, it has been approved for the primary treatment of invasive aspergillosis, salvage therapy for other mold infections caused by *S. apiospermum* and *Fusarium* spp., candidemia and other infections caused by *Candida* spp. (Table 1; Pappas et al., 2016; Patterson et al., 2016). Breakthrough infections caused by the members of the Mucorales have been reported.

Although the drug is generally well tolerated with only few side effects (hepatic [10–15%], transient visual [10–15%] and skin rash [1–5%]); non-melanoma skin cancer has been associated with voriconazole exposure shortly after the drug was approved by the US Food and Drug Administration, among organ (especially lung) transplant recipients taking voriconazole for prophylaxis and/or treatment of invasive fungal infections. (Table 2; Williams et al., 2014). The control of underlying patient characteristics is essential and patients should be educated about their increased risk of skin cancer. Screening for skin cancer and considering alternatives to voriconazole for patients at risk are highly recommended. For reported drug interactions see Table 3.

Posaconazole (SCH 56592)

Posaconazole is the product of a modification of the n-alkyl side chain of SCH 51048, which included a variety of chiral substituents (Fig. 3B). Posaconazole absorption from the intestinal tract is slow and peak serum concentrations are achieved 11–24 h after the actual dose. Posaconazole exhibits dose-proportional absorption up to 800 mg; dividing the dose and food or liquid supplements

Fig. 3 Chemical structures of three triazoles: (A) voriconazole, (B) posaconazole, and (C) ravuconazole (BMS-207147; ER-30346).

increase exposure. It has a large volume distribution (1774 L) and it is highly protein bound (>98%). Posaconazole has a prolonged elimination half-life (20–66 h); it is not extensively metabolized (approximately 14%) and is eliminated unchanged in the feces (66%). The in vitro fungistatic and fungicidal activities of posaconazole are similar to those of voriconazole and amphotericin B against yeasts, the dimorphic fungi, most opportunistic molds including the Mucorales, certain phaeoid fungi, and the dermatophytes.

Three posaconazole formulations (NOXAFIL, developed by Merck) have been approved by the FDA in USA for prophylaxis against invasive *Aspergillus* and *Candida* infections in high-risk patients (severely immunocompromised hematopoietic stem cell transplant [HSCT]) recipients with graft-versus-host disease (GVHD) or those with hematologic malignancies with prolonged neutropenia (low white blood cell counts) from chemotherapy: (i) an oral delayed-release tablet (100 mg; loading dose of 300 mg [three 100 mg tablets] twice daily on the first day, followed by a once-daily maintenance dose of 300 mg [three 100 mg tablets]); (ii) an i.v. formulation (18 mg/mL; for patients 18 years of age and older); and (iii) an oral suspension (40 mg/mL, dosed three times daily for patients 13 years of age and older). The tablet has higher bioavailability and more importantly it can be administered independent of food ingestion. The i.v. formulation will be beneficial for patients who are intolerant to oral posaconazole or patients who may need i.v. administration for other reasons. However, the incidence of fungal infections was not significantly different between patients receiving the tablet versus the oral suspension formulations (>500 patients) (Foruno et al., 2018). The most frequently reported adverse reactions are diarrhea (32%), hypokalemia (22%), fever (21%), increased hepatic enzymes and nausea (19%) (Table 2). Inducers of the UDP glucuronidation pathway may affect posaconazole plasma concentrations (Table 3). Posaconazole is generally well tolerated and serious adverse effects (most common, altered drug level, nausea, rash, and vomiting) have occurred in 8% of patients (<http://www.mercknewsroom.com/news-release/prescription-medicine-news/fda-approves-mercks-noxafil-posaconazole-injection-18-mgml-i-#sthash.kxV0QM7t.dpuf>).

Isavuconazole (BAL8557)

Isavuconazole (isavuconazonium sulfate, Cresemba®, Astellas Pharmaceuticals US, Inc., Northbrook, IL, USA) is a water soluble triazole that has been recently approved for fungal treatment. Isavuconazole inhibits ergosterol biosynthesis (enzymes 14- α -sterol demethylases A and B which are encoded by the CYP51A and B genes) and has a similar in vitro activity as the other triazoles against *Aspergillus* spp., other molds, including the Mucorales (zygomycetes), as well as *Candida* spp. and *C. neoformans* (Table 1). The global double-blind randomized clinical trial (516 patients) evaluated the safety and efficacy of once-daily isavuconazole versus twice-daily voriconazole for the primary treatment of invasive infections caused by *Aspergillus* spp. and other molds. Although isavuconazole was found to be non-inferior to voriconazole for the treatment of invasive fungal infections, it was documented that it had fewer drug-related adverse effects. Based on these results, the US FDA approved isavuconazole for the primary treatment of invasive aspergillosis and mucormycosis in adults; the European Medicines Agency (EMA) also approved this agent for the same infections in patients for whom amphotericin B is inappropriate. The licensed dosage is 200 mg three times a day for the first 2 days, then 200 mg daily (either i.v. or oral delivery). At steady state, the C_{min} is 3.9 ± 2 mg/L. Because it has activity against the Mucorales molds, e.g., the species of *Rhizopus*, *Mucor* and *Cunninghamella*, it could be used as a supplement of the medical-surgical treatment therapy for these infections (<https://www.fda.gov/downloads/advisorycommittees/committeesmeetingmaterials/drugs/ucm430748>).

The oral formulation has 98% bioavailability and its absorption is not influenced by food; the i.v. formulation lacks the solubilizing agent used for other azoles, cyclodextrin, which is associated with nephrotoxicity in patients with renal insufficiency. Although and unlike the other azoles, isavuconazole does not appear to exacerbate QT prolongation, “it can shorten the cardiac QT interval in a dose-related manner” and it is contraindicated in patients with familial/congenital short QT syndrome. Compared to voriconazole, isavuconazole has linear pharmacokinetics and is less prone to be the perpetrator drug or victim drug in the setting of drug–drug interactions with concomitantly administered drugs. Isavuconazole adverse events were statistically fewer than those of voriconazole (hepatobiliary, skin and eye disorders) and the most common events were nausea, vomiting, pyrexia (fever) and diarrhea (Desai et al., 2016; Keirns et al., 2017) (Table 2). Reports of cross reactivity of isavuconazole in patients with a history of acute liver injury from another azole are few but it is recommended that therapy should be started with caution as well as appropriate monitoring (NHI website, antifungal agents).

Due to the similarity of voriconazole and isavuconazole MICs, it has been concluded that the use of high doses of isavuconazole might be an option in patients infected with an *A. fumigatus* isolate for which an isavuconazole MIC of 2 μ /mL has been obtained, a value that is above the EUCAST susceptible endpoint of 1 μ /mL (Buil et al., 2018).

Terconazole

Terconazole was the first triazole marketed for the topical treatment of vaginal candidiasis and superficial dermatophyte infections (Table 1). Currently, it is only used for vulvovaginal candidiasis (0.4% and 0.8% vaginal creams and 80 mg vaginal suppositories).

Investigational triazoles

PC1244

The new triazole PC1244 was designed for topical or inhaled administration against *A. fumigatus* infections. It has potent in vitro activity against a variety of fungal pathogens including *A. fumigatus* WT and mutant isolates, *R. oryzae*, and *C. neoformans*. In vivo, when given once daily via intranasal administrations (3.2–80 μ g/mL) to temporarily neutropenic mice infected with *A. fumigatus*,

reduction of fungal load in the lung, galactomannan in serum and circulating inflammatory cytokines were observed. Given those results, it has potential as a novel treatment of lung *A. fumigatus* infections (Colley et al., 2018).

Other triazoles

The following triazoles were under clinical investigation, but are not longer being developed: saperconazole (R 66905), BAY R 8783, SCH 39304, SCH 51048, BAY 3783, and SDZ 89-485 were discontinued from further development due a variety of adverse side effects. Although Ibaconazole (CAS 187949-02-6) reached Phase II clinical trials, it does not appear to be under further development.

Cell Membrane as Antifungal Target: VT-1129, VT-1598 and VT-1161

VT-1129, VT-1598 and VT-1161 (Viamet Pharmaceuticals) are novel class of metalloenzyme inhibitors that, like the azoles and triazoles, inhibit the enzyme responsible for the final step of ergosterol biosynthesis, the fungal 14α -ergosterol demethylase (CYP51). The idea was to have molecules than are more specific for the fungal than the human CYP51 enzyme. It is expected that the selectivity for fungal cells may decrease the risk for toxicity at high doses of drug. VT-1129 is more selective for *Cryptococcus* cells and VT-1161 is for *Candida* cells. On the other hand, VT-1598 is in preclinical development for treatment of coccidioidomycosis. VT-1161 has completed Phase 2b clinical trials for the treatment of recurrent vulvovaginal candidiasis (RVVC) and onychomycosis (www.viamet.com).

The Allylamines

The allylamines act by inhibiting squalene epoxidase, which results in a decrease in the ergosterol content and an accumulation of squalene.

Terbinafine and Naftifine

Terbinafine (Fig. 2D) is the most active derivative of this class of antifungals. It has an excellent in vitro activity against the dermatophytes and other filamentous fungi, but its in vitro activity against the yeasts is controversial. It follows linear pharmacokinetics over a dose range of 125–750 mg; drug concentrations of $0.5\text{--}2.7\ \mu\text{g mL}^{-1}$ are detected 1 or 2 h after a single oral dose. Terbinafine has replaced griseofulvin and ketoconazole for the treatment of onychomycosis and other infections caused by dermatophytes (oral and topical). It is also effective for the treatment of vulvovaginal candidiasis. It is usually well tolerated at oral doses of 250 and 500 mg per day and the side effects (10%) are gastrointestinal and cutaneous. The metabolism of terbinafine may be decreased by cimetidine and increased by rifampin. Pharmacokinetics and poor activity have limited the use of naftifine to topical treatment of dermatophytic infections.

The Benzylamines, Thiocarbamates, and Dithiocarbamates

The benzylamine, butenafine, and the thiocarbamates, tolnaftate, tolclate, and piritetrate, also inhibit the synthesis of ergosterol at the level of squalene. Their clinical use is limited to the topical treatment of superficial dermatophytic infections. The Bordeaux mixture (reaction product of copper sulfate and lime) was the only fungicide used until the discovery of the dithiocarbamate fungicides in the mid-1930s. Of those, mancozeb and thiram are widely used in agriculture, but because they are only surface-acting materials frequent spray applications are required. Ferbam, maneb, and zineb are not used as much.

The Benzimidazoles and Methylbenzimidazole Carbamates

A great impact on crop protection was evident with the introduction of the benzimidazoles and other systemic (penetrate the plant) fungicides. These compounds increased spray intervals to 14 days or more. The methylbenzimidazole carbamates (MBCs; carben-dazim, benomyl, and thiophanate) inhibit nuclear division and are also systemic agricultural fungicides. However, since MBC-resistant strains of *Botrytis cinerea* and *Penicillium expansum* have been isolated, these compounds should be used in combination with *N*-phenylcarbamate or agents that have a different mode of action.

The Morpholines

The morpholines interfere with 14α reductase and $7,8$ isomerase enzymes in the ergosterol biosynthetic pathway, which leads to an increase in toxic sterols and an increase in the ergosterol content of the fungal cell.

Amorolfine

Amorolfine, a derivative of fenpropimorph, is the only morpholine that has a clinical application for the topical treatment of dermatophytic infections and candidal vaginitis.

Fenpropimorph, Tridemorph, and Other Morpholines

Protein binding and side effects have precluded the clinical use of these morpholines, but they are important agricultural fungicides.

The Pyridines (Pyrifenoxy and Buthiobate)

The pyridines are another class of antifungal agents that inhibit lanosterol demethylase; pyrifenoxy and buthiobate are agriculture pesticides.

The Echinocandins, Pneumocandins, and Papulocandins

The echinocandins and papulocandins are naturally occurring metabolites of *Aspergillus nidulans* var. *echinulate* (echinocandin B), *A. aculeatus* (aculeacin A), and *Papularia sphaerosperma* (papulocandin). They act specifically by inhibiting the synthesis of fungal (1,3)-glucan synthetase, which results in the depletion of glucan, an essential component of the fungal cell wall.

The Papulocandins

The papulocandins A–D, L687781, BU4794F, and chaetiacandin have in vitro activity only against *Candida* spp. but poor in vivo activity, which precluded clinical development.

The Echinocandins and Pneumocandins

Echinocandin resistance, molecular mechanisms of resistance

The echinocandins include echinocandins, pneumocandins, aculeacins, mulundo- and deoxymulundocandin, sporiofungin, vWF 11899 A–C, and FR 901379. Among them, the echinocandins have better in vitro and in vivo antifungal activity than the papulocandins and pneumocandins. Anidulafungin, caspofungin and micafungin are indicated for the treatment and/or prophylaxis of candidemia in nonneutropenic patients, esophageal candidiasis, and/or salvage therapy for aspergillosis, especially in patients who had been treated with an azole and/or for infections caused by *C. glabrata* and *C. krusei*. Currently, another two echinocandins are under development for vulvovaginal, invasive candidiasis and aspergillosis (Ibrexafungerp [SCY-078] and rezafungin [formerly CD101]) as well as potential prophylactics for aspergillosis in immunocompromised patients (rezafungin) (Table 1) (Sandison et al., 2017; Sofjan et al., 2018; <https://www.scynexis.com/pipeline>). Other applications are provided under the description of each agent when applicable, but higher doses are recommended for patients with endocarditis and other cardiovascular infections, e.g., caspofungin 50–150 mg/day, micafungin 100–150 mg/day, or anidulafungin 100–200 mg/day. Although *C. parapsilosis* and *C. guilliermondii* have less in vitro susceptibility to the three echinocandins than other *Candida* species, the concern that *C. parapsilosis* infections may be less responsive to echinocandin therapy has not been clearly demonstrated. These three agents are not effective for the treatment of infections caused by *C. neoformans*, *T. beigeli*, *Fusarium* spp., and the Mucorales.

Echinocandin resistance has been reported in patients infected with *C. albicans*, *C. glabrata*, *C. tropicalis*, and *C. krusei*. Echinocandin resistance to *C. glabrata* has increased from 4.9% to 12.3% between 2001 and 2010 including reports of cross-resistance to both echinocandins and azoles. Such in vitro and clinical resistance has been associated with point mutations in the *FKS1* and/or *FKS2* genes (Table 4; Spampinato and Leonardi, 2013) which encode the glucan synthase complex. In contrast to *Candida* spp., the relationship between *FKS1* gene mutations and high caspofungin and other echinocandins MECs (minimal effective concentrations) for *Aspergillus* spp. is yet to be determined. Caspofungin MECs of ≥ 1 $\mu\text{g/mL}$ for *A. fumigatus* were obtained from breakthrough infections in patients receiving this agent. Although EUCAST clinical breakpoints and/or CLSI ECVs are available for the three licensed echinocandins and most common *Candida* spp. (including *C. glabrata*), antifungal susceptibility testing of caspofungin by both reference methods is not recommended for *Candida* spp. due to interlaboratory variability problems. However, ECVs for the widely used Sensititre YeastOne colorimetric broth microdilution method have been proposed for most common *Candida* species and the three echinocandins (Espinel-Ingroff et al., 2015). As far as the filamentous fungi, EUCAST and CLSI categories are available for some *Aspergillus* spp. (CLSI document M59, 2018; Espinel-Ingroff and Turnidge, 2016; www.eucast.org).

Anidulafungin (VER-002; LY303366, V-Echinocandin)

Anidulafungin is a semisynthetic cyclic lipopeptide which resulted from an increase of aromatic groups in the cilofungin sidechain (Fig. 4A). It has high potency and oral and parental bioavailability. In laboratory animals, peak levels in plasma (5 or 6 h) of

Fig. 4 Chemical structures of (a) anidulafungin (VER-002; (b) V-echinocandin LY303366), (c) caspofungin (L 743872 or MK-0991), micafungin.

0.5–2.9 µg mL⁻¹ have been measured after single doses of 50–250 mg/kg. In humans, peak levels of 105–1624 ng mL⁻¹ are measured after oral administrations of 100–1000 mg/kg. Anidulafungin pharmacokinetics are linear with a short distribution half-life (0.5–1 h) and a volume distribution of 30–50 L. The terminal elimination half-life is about 40–50 h and clearance is about 1 L/2 h. Tissue concentrations are usually higher than those in plasma in animals. Systemic exposures of anidulafungin (post i.v. doses) are dose proportional and this agent is moderately protein bound in humans.

Anidulafungin has good in vitro activity against a variety of yeasts, including isolates resistant to itraconazole and fluconazole, and *Aspergillus* spp. MECs for certain molds are higher than those of the azoles, but its fungicidal activity against some species of *Candida* is superior to those agents. Laboratory abnormalities in liver functions have been observed, but no clinically relevant drug–drug interactions have been observed with drugs likely to be co-administered with anidulafungin.

Caspofungin (MK-0991 or L743872)

Caspofungin (Fig. 4B) is the product of a modification of L733560 and was selected for evaluation in clinical trials in humans. Caspofungin is water soluble, highly protein bound (97%) with a half-life that ranges from 5 to 7.5 h and drug concentrations are usually higher in tissue than in plasma. As for anidulafungin and micafungin, caspofungin exhibits favorable dose dependent linear pharmacokinetics and only i.v. formulations are available. Caspofungin has fungistatic and fungicidal activities similar to those of anidulafungin against most *Candida* spp. and lower activity against the dimorphic fungi. It also has fungistatic in vitro activity against some of the other molds, especially *Aspergillus* spp. The drug is mostly well tolerated, but histamine release, mild hepatotoxicity, fever, nausea, vomiting, and rash have been reported (Table 2). Caspofungin (70 mg loading and 50 mg maintenance doses) has been approved for refractory invasive aspergillosis or for patients intolerant to other agents and empiric therapy for febrile neutropenic patients unresponsive to antibacterial therapy (Table 1). Caspofungin has been evaluated for the prophylaxis of invasive candidiasis; the differences between the drug and placebo were 16.7% (14/84 patients) versus 9.8% (10/102 patients), respectively. The three echinocandins have been recommended for this purpose only as an alternative to fluconazole (*Candida* infections). (Pappas et al., 2016).

Micafungin (FK 463)

Micafungin is a semisynthetic derivative of a naturally occurring lipoprotein that was synthesized by a chemical modification from a product of the mold *Coleophora impedir*. As the other echinocandins, it has in vitro activity against *Candida* and *Aspergillus* species. The drug is well tolerated (Table 2). It is protein binding (99%) and plasma concentrations attain a steady state by day 4 with repeated doses. Micafungin has been approved for the prophylaxis of *Candida* infections in patients undergoing HSCT (50 mg daily maintenance) (Table 1). There have been reports of clinical failures and breakthrough infections and high MICs in patients receiving micafungin therapy due to the development of drug resistance associated in some cases with specific mutations in the FKS protein component of the glucan synthase enzyme.

Ibrexafungerp

Ibrexafungerp (Scynexis, NJ, USA; formerly SCY-078) is a triterpenoid agent that also inhibits the beta 1,3 glucan synthase enzyme. It is the first oral glucan synthase inhibitor derivative of the natural product enfumafungin under development for the treatment of systemic candidiasis, including candidemia, and aspergillosis. Glucan synthase inhibitors have been effective in treating invasive fungal infections in a hospital setting, but currently are only available as an intravenous dosing option. Ibrexafungerp has in vitro activity against *Candida* spp. (including FKS mutants and *C. auris* biofilm). In a model of neutropenic rabbits, this agent compared well with isavuconazole for the treatment of experimental invasive aspergillosis. In vivo activity was also demonstrated in a murine model of invasive aspergillosis when animals were infected with both wild type and mutant *A. fumigatus* isolates. Phase II clinical trial for vulvovaginal candidiasis (VVC) indicated that the 600 mg dose of ibrexafungerp (given as two doses of 300 mg 12 h apart) is the optimal dose and it was a well-tolerated regimen that provided overall strong clinical and mycological outcome effect when compared to fluconazole. Preliminary data of a second Phase II clinical trial indicated that this agent also has good activity against invasive candidiasis with few drug interactions as compared with fluconazole (no effects on tacrolimus or rosiglitazone); data are not yet available for the comparison with micafungin. In addition, it has demonstrated synergistic activity in combination with isavuconazole for the treatment of invasive pulmonary in neutropenic rabbits ("Advances against aspergillosis", Lisbon, Portugal, February 2018; <https://www.scynexis.com/pipeline>). However, the development of the IV formulation has been delayed.

Rezafungin

Rezafungin acetate is another new echinocandin under clinical evaluation (Cidara Therapeutics; formerly CD101 IV). The safety and pharmacokinetic of rezafungin acetate was evaluated in a dose-escalation study (50 to 400 mg once a week) in healthy adults who were given the drug over 1 h. A higher incidence of mild and transient adverse side effects and transient infusion reactions in the 400-mg dose group than those in 200-mg dose were reported (Table 2). The efficacy of rezafungin versus daily standard caspofungin is being evaluated in a Phase II study for candidemia and/or invasive candidiasis-bridging extension (STRIVE: IV 400 mg rezafungin once weekly for up to 4 weeks or 400 mg on week 1 and 200 mg thereafter). The data indicated that rezafungin is safe and effective at separate doses regarding both clinical and microbiological outcome. In a model of *C. auris* candidiasis, this agent also showed antifungal activity as compared to those of amphotericin B and micafungin. Due to the in vitro activity against azole-resistant *Aspergillus*, the high concentrations of rezafungin (including isolates harboring TR34/L98H mutations) distributing into the lungs and the rationale for dose selection also indicated the potential use of this agent for the prevention of *Aspergillus*, *Candida* and

Pneumocystis infections in BMT patients (Sandison et al., 2017; Sofjan et al., 2018; Hager et al., 2018; clinicaltrials.gov/ct2/show/study/NCT02734862). The Phase III program of rezafungin clinical trials will address the efficacy of this agent for difficult-to-treat, invasive *Candida* infections.

Glycosylphosphatidylinositol Biosynthesis Inhibition Inhibitors (GPI) for Clinical Use

E1210/APX001

E1210/APX001, discovered by Eisai, Ltd., Japan, has entered Phase 1 to Phase II clinical trials under Amplyx Pharmaceuticals, Inc. It inhibits the inositol acylation step in fungal GPI biosynthesis, interfering with the fungal cell wall growth, hyphal elongation, and fungal attachment to the biological substrates. It has a broad spectrum of in vitro activity against both species of *Fusarium* and *Scedosporium* (including *Lomentospora prolificans*), *Paecilomyces lilacinus* and other species usually resistant to triazoles and polyenes. It also has demonstrated efficacy in murine models of oropharyngeal and disseminated candidiasis and fusariosis (*F. solani*) as well as pulmonary aspergillosis (*A. fumigatus* or *Aspergillus flavus*). In rats, it was well tolerated at 100 mg/kg and up to 300 mg/kg (Osherov and Kontoyiannis, 2017; McCarthy et al., 2017).

Gepinacin

Gepinacin is a monocarboxylic amide that inhibits acyltransferase, an enzyme that anchors GPI during its biosynthesis producing stress to the endoplasmic reticulum. Gepinacin does not affect the viability of mammalian cells and it has been reported that increases the immunogenicity against *C. albicans* (Osherov and Kontoyiannis, 2017).

Fungal Mitochondria Inhibitor

T-2307

T-2307 (Toyama Chemical Co., Tokyo, Japan) is an arylamidine small molecule similar to pentamidine. Its target is the fungal mitochondria (*Candida* cells) leading to membrane loss. T-2307 exhibits potent in vitro as well as in vivo activity in murine models of *C. albicans* systemic infection (100% two-week survival, 0.02 mg/kg), *C. neoformans* (>70% two-week survival, 0.3 mg/kg), and *A. fumigatus* (>80% two-week survival, 1 mg/kg). In Phase I clinical trials in healthy volunteers, T-2307 demonstrated good safety and tolerability, and pharmacokinetics (<https://clinicaltrials.gov/ct2/show/NCT02289599>; Osherov and Kontoyiannis, 2017).

Zinc Inhibitors

ZAC307 and ZAC989

Two novel zinc27 attenuating compounds, ZAC307 and ZAC989, have shown both in vitro and in vivo antifungal activity in a kidney candidiasis model. Genetic analysis suggested that these ZAC molecules interfered or obstructed the expression of the genes encoding the major components of *A. fumigatus* zinc uptake system, suggesting the disruption of zinc homeostasis as their likely mode of action (Cohrt et al., 2018).

The polyaminocarboxylate molecule

Of a total of 116 molecules that had inhibitory effects on fungal growth, six molecules were further screened. Although all had good in vitro antifungal activity, only one of the polyaminocarboxylates molecules significantly improved in vivo survival in an immunosuppressed murine model of pulmonary aspergillosis. This small molecule also showed low toxicity and it could become a new treatment for invasive fungal infections. (See Laskaris et al., 2018).

Acylhydrazones

The BHBM D13 derivative

The acylhydrazone BHBM derivatives target the fungal sphingolipid pathway. Of the total of 19 derivatives of BHBM that have been screened, three of them had specific in vitro activity against *C. neoformans* and toxicity was low against mammalian cells. Of those three, the molecule denominated D13 showed better in vivo activity in various experimental models (cryptococcosis, candidiasis and pulmonary aspergillosis), suitable pharmacokinetic properties and was able to pass through the blood brain barrier (See Lazzarinia et al., 2018).

The Orotomides

Olorofim (F901318)

Olorofim (F901318; F2G Limited, UK) is the first in a new class of antifungal agents called the orotomides. It inhibits the enzyme dihydroorotate (*DHODH/URA1*) catalyzing the fourth enzymatic step of pyrimidine biosynthesis. Although it has shown good

in vitro activity (MICs mostly below 1 µg/mL) against azole-resistant molds, *Aspergillus* spp., *Scedosporium* spp., *Fusarium* spp., and the dimorphic fungal species, it did not show activity against the Mucorales or *Candida* spp. It was effective in a neutropenic model of murine *A. terreus* infection. Phase I clinical trials indicated that a single dose of olorofim administered IV at up to 4 mg/kg was well tolerated and no adverse effects were observed. Although it was announced that this agent could be moving to Phase IIa studies for the prophylaxis (in combination with caspofungin) of neutropenic patients with acute myeloid leukemia, no data are available yet (Osherov and Kontoyiannis, 2017; Lackner et al., 2018).

Other Approach to Antifungal Drug Development

Salicylanilide and niclosamide compounds

Recently, a new approach to antifungal therapy was investigated. A total of 678 small molecules were evaluated for their potential antifungal activity against the invasive hyphal form of *C. albicans*. Among those, the halogenated salicylanilide (N1-[3,5-dichlorophenyl]-5-chloro-2-hydroxybenzamide) and niclosamide compounds exhibited antifungal activity against resistant *C. albicans* hyphae and biofilms, as well against *C. auris*. In addition, niclosamide protected the intestinal epithelial cells from *C. albicans* tissue invasion. Since the safety of niclosamide is well established in humans as an FDA-approved anthelmintic, this therapeutic could become the first clinically approved fungal anti-virulence agent (Garcia et al., 2018).

Dimethomorph and fluazinam

Dimethomorph is a cinnamic acid derivative for use against *Plasmopara viticola* on vines and *Phytophthora infestans* on tomatoes and potatoes; it is not cross-resistant to phenylamides (systemic controllers of *Phycomycetes* plant infections). Fluazinam is used in vines and potatoes but also acts against *Botrytis cinerea* as an uncoupler of oxidative phosphorylation.

The phthalimides

The discovery of captan in 1952 and later of the related captafol and folpet initiated the proper protection of crops by the application of specific fungicides. Captan is also used to treat dermatophytic infections in horses and cattle, but it causes skin sensitization in horses.

Antigenic Variation in Bacterial Pathogens

Erica L Raterman and Ann E Jerse, Uniformed Services University, Bethesda, MD, United States

Glossary

Antigenic variation The process by which pathogens change the sequence of their antigenic molecules to evade clearance by the host immune response during the course of an infection.

Epigenetic modification Alterations made to DNA, usually by methylation or alteration of chromatin structure, which effect the expression of a gene but do not change its genetic sequence. These changes in expression patterns are heritable.

Gene conversion Whole or partial gene sequences, termed donor sequences, are copied from one unexpressed location in the genome to another expressed location, termed the acceptor gene. The donor gene sequence remains unchanged. Also called duplicative homologous recombination or duplicative transposition.

Gene inversion The reversible switching of a promoter element by specific recombinases that either turn expression of a gene “on” or “off”, depending on the orientation of the promoter.

Phase variation The reversible switch between “on” and “off” expression phases by genetic or epigenetic mechanisms in which the expression phase is heritable by daughter cells.

Reciprocal recombination The mutual exchange of genetic sequences between donor and expression sites.

Mechanisms of Antigenic Variation

Gene Conversion

Gene conversion is the best studied and most widely used genetic mechanism that microorganisms employ to achieve antigenic variation of their surface proteins. Microorganisms that undergo this mechanism can encode up to hundreds of copies of one gene, each of which has nucleic acid differences in what are termed “variable regions” of their nucleotide sequence. Typically, one copy of the gene is expressed at a time under the control of a single promoter, which is termed the acceptor sequence. Silent copies of the gene or smaller variable regions of the gene, which lack a promoter and are termed functional pseudogenes or donor sequences, are encoded at another location in the genome. Recombination events occur in which the acceptor copy of the gene is replaced in whole or in part by one of the donor copies by the process of duplicative homologous recombination. The genetic exchange is unidirectional in that the sequence of the expressed acceptor gene copy is changed while the sequence of the silent donor copy remains unchanged. Specifically, the donor strand invades the acceptor sequence and a heteroduplex is formed. Mismatch repair and synthesis of the complementary sequence then occurs to replace the acceptor sequence with the new donor sequence, resulting in a new expressed copy of the gene and leaving the donor site unchanged (Fig. 1(A)). A few examples and variations of the gene conversion mechanism in different pathogenic organisms are illustrative of the process.

A classic example of antigenic variation in bacteria is pilin antigenic variation in *Neisseria gonorrhoeae*. *N. gonorrhoeae* infects the urogenital tract to cause gonorrhea, and the type IV pilus is important for successful infection by mediating adherence to epithelial cells and its role in host cell signaling and twitching motility. The major subunit of the type IV pilus is encoded by *pilE*, which displays one of the highest rates of reported antigenic variation in bacteria. PilE antigenic variation occurs by the mechanism of segmental gene conversion. The *N. gonorrhoeae pilE* gene is expressed from one to two loci and undergoes unidirectional exchange of genetic sequence with silent truncated variant copies found elsewhere in the chromosome within what are called *pilS* loci. There are 5 different *pilS* loci, each of which contains 17–19 silent copies of *pilE*. The conserved N-terminal domain of *pilE* is not encoded in the silent *pilS* cassettes and remains unchanged after the recombination event. The hypervariable loop region and the hypervariable tail region encoded further downstream in *pilE* display the highest rate of sequence variation in the silent *pilS* copies, with 1–200 bp of sequence flanked by 3–68 bp of homologous regions transferred during each recombination event. In addition to recombination between the *pilE* gene and *pilS* copies elsewhere on the chromosome (intragenic recombination), *intergenic* recombination may also occur between *pilE* and *pilS* copies within genomic DNA taken up from lysed gonococci.

Further investigation of the mechanism of *pilE* antigenic variation revealed that components of the homologous recombination machinery as well as several other elements are required for recombination between *pilE* and the *pilS* copies. The RecA, RecO and RecR proteins, which are involved in homologous recombination, are required for antigenic variation of *pilE* as are the two *cis*-acting sequences termed the Sma/Cla repeat, a 65 bp sequence that may provide an extended region of homology for the recombination event, and the G4-forming sequence, which is a 16 bp G-rich sequence that forms a guanine quartet structure that may initiate the homologous recombination event at the *pilE* locus. Formation of the G4-quartet structure requires transcription of a small RNA that initiates its transcription within the G4 structure-forming sequence to activate formation of the G4-quartet structure. Antigenic variation of the *pilE* gene sometimes results in pilus phase variation (the turning ‘on’ or ‘off’ of gene expression or functional protein

A. Gene Conversion**B. Reciprocal Homologous Recombination****C. Nested DNA Inversion**

Fig. 1 Mechanisms of antigenic variation. Antigenic variation of bacterial immunogens can be achieved through several different mechanisms. (A) Gene conversion uses unexpressed gene cassettes located elsewhere in the genome to copy a new sequence variant of a gene, either wholly or partially, into the expression site with a promoter (arrow). (B) Reciprocal homologous recombination is related to gene conversion, except the silent variant gene and the original expressed gene switch places in the expression and silent sites after the recombination event. (C) Nested DNA inversion transposes the promoter instead of the coding region of the gene to a new site within a contiguous array of gene variants to achieve expression of a new variant. A recombinase site is encoded within the conserved sequence (purple box), which also contains the promoter (arrow), upstream of each oppositely oriented gene variant. To achieve transfer of the conserved sequence with the promoter, the recombinase sites are aligned and the DNA between the two recombinase sites is reversed, which results in the rearrangement of the cassettes and the inversion of the promoter to drive expression of a new gene variant. Portions of panel C were modeled on information provided in Fig. 3 of Dworkin, J., Blaser, M.J., 1997. Nested DNA inversion as a paradigm of programmed gene rearrangement. *Proceedings of the National Academy of Sciences of the United States of America* 94 (3), 985–990.

production), in that PilE subunits that cannot be assembled into functional pilin can result due to the introduction of missense or nonsense mutations during the recombination event.

Antigenic variation by whole gene conversion occurs in the *vlp* and *vsp* genes of *Borrelia hermsii* and *Borrelia recurrentis*, respectively, which cause the tick-borne disease known as relapsing fever. The *vlp* and *vsp* genes encode variable large and small surface lipoproteins that are likely involved in the host-pathogen interactions. A single expression site for each gene is found on a plasmid, which can recombine with 38 *vlp* and 21 *vsp* pseudogene copies encoded in 10 genetic clusters on 5 different plasmids. Each pseudogene copy encodes the complete gene and ribosome binding site sequence and shares upstream and downstream homology sequences that allow the recombination event to occur. Expression of new *vsp* and *vsl* variants occurs at a high frequency, and each new wave of the relapsing infection is mostly dominated by bacteria that express one *vsp* or *vsl* variant. The *vsp* and *vsl* genes are only expressed in the mammalian bloodstream, suggesting an additional layer of genetic regulation that is host-restricted. Likewise, *Anaplasma phagocytophilum*, another tick-borne pathogen and the causative agent of human granulocytic anaplasmosis, uses gene conversion as a mechanism of antigenic variation. The Msp2 protein of *A. phagocytophilum* is a major surface protein involved in host cell attachment, and *A. phagocytophilum* uses segmental gene conversion to replace the *msp2* “acceptor sequence”, which is expressed, with the whole sequence of one of ~100 pseudogenes encoded elsewhere in the genome.

Another *Borrelia* spp. and another spirochete, *Treponema pallidum*, undergo antigenic variation of key surface proteins. The *vsIE* gene of *Borrelia burgdorferi*, the causative agent of Lyme disease, shares similarity with the *vsl* and *vsp* genes, but, like *N. gonorrhoeae* *pilE*, undergoes antigenic variation via a segmental gene conversion mechanism based on an array of contiguous silent pseudogenes encoded on a linear plasmid. The silent pseudogenes only encode the middle segment of *vsIE*, and variable lengths of the expressed *vsIE* gene are replaced during the segmental recombination events. Unlike relapsing fever, Lyme disease is a chronic disease in which the infection is maintained at low levels. The chronic nature of the disease coupled with the generation of new *vsIE* variants through continuous recombination events results in an array of bacterial clones, each of which produces an antigenically different *VsIE* protein. Like *B. burgdorferi*, *Treponema pallidum*, the causative agent of syphilis, causes chronic disease. *T. pallidum* *tpoK* also employs a

segmental gene conversion system in which only 7 variable regions of the acceptor gene are replaced by one of 47 variable region variants encoded in another gene, *tprD*.

Reciprocal Homologous Recombination

Although much less frequently observed in microorganisms, reciprocal homologous recombination is similar to gene conversion in that homologous recombination is used to exchange a gene at a single expression site with variant pseudogene sequences located elsewhere in the genome. However, the recombination event is reciprocal, meaning that the pseudogene variant sequence is not merely used as a template to copy the sequence into the expression site, but is exchanged with the gene sequence originally encoded in the expression site. The result is that the original gene variant is now located in the genetic position that the pseudogene formerly occupied and the former pseudogene sequence is now the gene in the expression site (Fig. 1(B)).

The surface-exposed proteins MgpB and MgpC of *Mycoplasma genitalium*, which are involved in adhesion, motility and cell division, undergo antigenic variation using the reciprocal homologous recombination mechanism within their genes. The *mgpB* and *mgpC* genes have alternating conserved and variable regions and are located in a single expression site. Partial pseudogenes termed MgPa repeats are located in nine different loci in the genome and share homology to 3 regions of the *mgpB* gene and 2 regions of the *mgpC* gene. Segments of the MgPa repeats are exchanged with the variable regions in *mgpB* and *mgpC*, which leads to increased genetic diversity. Because the *M. genitalium* genome is relatively small (580 kb, 470 genes) compared to other microorganisms, this mechanism of homologous recombination offers a compact solution for allowing genetic diversity and antigenic variation while maintaining a small genome that is not amenable to hosting an array of full-length pseudogenes. The dedication of 4.7% of the space-limited genome to the MgPa operon, however, highlights the importance of the antigenic variation of MgpB and MgpC to the survival of *M. genitalium* in the host.

Nested DNA Inversion

The nested DNA inversion mechanism of antigenic variation involves the inversion of a promoter along with one or more tightly clustered variations of a gene flanking the promoter element (Fig. 1(C)). The surface layer protein (SLP) encoded by *sapA* of *Campylobacter fetus* is involved in the resistance of the host innate immune response by inhibiting the binding of the complement system protein C3b and is one of the best-studied examples of nested DNA inversion. The 6.2 kb promoter element is flanked by 5–9 variants of *sapA* in opposite orientations. One or more of the *sapA* variants are inverted along with the promoter element, which can ultimately result in the expression of all of the *sapA* variants. The promoterless *sapA* variants contain a 626 bp 5' conserved region and a 26 bp 3' conserved region, which allows each variant to be recognized and inverted with the promoter element. Intragenic recombination is also possible between some variants of *sapA*, which can lead to new *sapA* variant formation.

Hypermutation

The accumulation of point mutations in a gene at a greater frequency than that which occurs in the rest of the genome can also lead to antigenic variation. The *vsp* and *vsl* genes of *B. hermsii* accumulate mutations at a rate of 0.04 per cell per generation but only in the expressed gene variants and not in the silent pseudogenes. M proteins involved in adhesion and invasion of host cells by *Streptococcus* spp. have hypervariable regions encoded in the N-terminal portion of the gene that sustain frequent point mutations that ultimately result in the generation of new M serotypes. The exact mechanism(s) by which the organisms direct the hypermutation of these specific regions remains unclear (Table 1).

Table 1 Mechanisms of antigenic variation and example organisms

Species	Gene	Surface antigen
<i>Whole gene conversion</i>		
<i>Neisseria gonorrhoeae</i>	<i>pil</i>	Type IV pili
<i>Borrelia hermsii</i> <i>Borrelia recurrentis</i>	<i>vsp</i> , <i>vlp</i>	Variable small protein Variable large protein
<i>Anaplasma phagocytophilum</i>	<i>msh2</i>	Outer membrane protein
<i>Segmented gene conversion</i>		
<i>Borrelia burgdorferi</i>	<i>vlsE</i>	Variable major protein-like sequence expressed
<i>Treponema pallidum</i>	<i>tprK</i>	Putative outer membrane protein
<i>Reciprocal homologous recombination</i>		
<i>Mycoplasma genitalium</i>	<i>mgpB</i> , <i>mgpC</i>	Adhesion proteins

<i>Streptococcus</i> spp.		M protein

Mechanisms of Phase Variation

Gene Inversion

Phase variation through sequence inversion most often occurs at loci that encode pilin or flagellar structural units and is accomplished by inversion of the promoter element between 'on' and 'off' states. One or several site-specific recombinases that recognize a specific sequence in the promoter element are employed to invert the DNA region (Fig. 2(A)). For example, the promoter upstream of *fimA*, which encodes the major structural unit of type I fimbriae of uropathogenic *Escherichia coli*, is part of the *fimS* invertible element. The *fimS* sequence is flanked by inverted repeats whose sequence is recognized by the FimB and FimE recombinases. FimB can flip *fimS* to either the 'off' or 'on' orientation to prevent or drive expression of *fimA*, respectively. FimE can only switch *fimS* from the 'on' to 'off' position. Because FimE exhibits higher activity than FimB, *fimA* is typically not expressed until adhesion is required and signals from the environment alter the activity or expression of FimB and FimE to cause a shift in the balance from the 'off' to 'on' position. These environmental signals include growth on solid or in liquid medium, osmolarity, and pH, which all affect the expression of *fimB* and *fimE*, and temperature, which differentially affects the activity of FimB and FimE.

A second example of phase variation by gene inversion is the flagellar locus of *Salmonella* spp. Two sequentially distinct flagellin subunits, FljC and FljB, are alternately expressed due to the Hin recombinase-mediated inversion of an 800 bp region containing the *fljB* promoter. When the *fljB* promoter is oriented in the 'on' position, both *fljB* and *fljA* are transcribed to produce type B flagella, and FljA represses expression of *fliC*. When the *fljB* promoter is in the 'off' position, *fliC* is transcribed to produce type C flagella. Coordinated phase variation of pili and flagella allow bacteria to adapt to environmental cues by using the 'stick or swim' switch mechanism. In a favorable environment, the bacteria may promote adherence through increasing expression of pili genes and decreasing expression of flagellar genes so that the bacteria can colonize a host surface and perhaps form biofilms that are resistance to host defenses and antibiotics. If the environment becomes unfavorable, the bacteria can then increase production of flagella expression and decrease production of adherent pili, thus promoting a planktonic lifestyle in which new host sites can be encountered and colonized.

A. Genetic Inversion

B. Epigenetic Modification

C. Slipped-strand Mismatching

Transcriptional

Translational

Fig. 2 Mechanisms of phase variation. Phase variation is related to antigenic variation but involves turning gene expression 'on' or 'off' instead of recombination with silent variant gene copies. (A) Genetic inversion uses a recombinase that recognizes specific repeat sequences on the edges of an invertible element, which includes a portion of the promoter (arrow), to flip the promoter into an orientation that either allows or inhibits expression of the gene. (B) Epigenetic modification, such as through methylation of GATC sites in the promoter region, alters the ability of DNA binding proteins to recognize their binding sites. In the example, methylation of the base pairs prevents binding of a transcriptional inhibitor and allows RNA polymerase to bind the promoter and initiate transcription. (C) Slipped-strand mismatching alters expression and translation by 'slipping' of the DNA polymerase during DNA replication. Transcriptional changes occur when the DNA polymerase slips either backwards or forwards on multiple repeats found in the promoter region before the transcriptional start site of a gene. The RNA polymerase is only able to transcribe the gene when the promoter is the appropriate length. Translational changes occur when the DNA polymerase slips either backwards or forwards on multiple repeats found in the coding region of a gene. Depending on the insertion or deletion of base pairs, the RNA polymerase will then transcribe either the correct, in frame sequence of the gene or the incorrect, out of frame sequence of the gene that will result in either a truncated or nonfunctional protein. Portions of panel C were modeled on information provided in Fig. 2 of Deitsch, K.W., Lukehart, S.A., Stringer, J.R., 2009. Common strategies for antigenic variation by bacterial, fungal and protozoan pathogens. *Nature Reviews Microbiology* 7 (7), 493–503. <https://doi.org/10.1038/nrmicro2145>.

Epigenetic Modification

Phase variation can also be achieved by epigenetic modifications of the DNA sequence surrounding the pilin gene. This mechanism is common to a large group of pili operons. For example, expression of the mutligene *pap* operon in uropathogenic *Escherichia coli* that encodes Pap pili (pyelonephritis-associated pili) is controlled by the methylation status of two GATC sites distal and proximal to the promoter that drives expression of the Pap pili assembly and structural genes. When *pap* gene expression is in the phase 'off' state, the transcriptional regulator Lrp is bound to the promoter region at sites that prevent methylation of the proximal GATC sequence, thus preventing transcription. In the phase 'on' state, Lrp binds to the distal portion of the *pap* promoter, occluding the distal GATC site and allowing methylation of the proximal GATC site. Methylation of the proximal GATC site then allows transcription of the *pap* genes to proceed (Fig. 2(B)). Phase variation of Pap pili, which mediate bacterial adhesion to the α -D-galactopyranosyl-(1-4)- β -D-galactopyranoside moiety present on cells lining the upper urinary tract, allows the bacteria to colonize the kidneys to cause pyelonephritis.

Slipped-Strand Mispairing

Deletion or insertion of short sequence repeats (SSR) in the promoter or coding region of a gene can cause phase variation through a mechanism called slipped-strand mispairing. The SSR are repetitive DNA segments of either a single nucleotide or multiple nucleotides. When the number of SSR is altered within a promoter region, the mechanism is specified as transcriptional slipped-strand mispairing because the ability of RNA polymerase to bind the promoter to initiate transcription is either enhanced or inhibited. Alteration of a SSR located in the coding region is termed translational slipped-strand mispairing due to the insertion or deletion of base pairs that, when translated by the ribosomal machinery, result in a protein that is either functional, nonfunctional, or truncated (Fig. 2(C)). The number of these repeats is determined during DNA replication when the DNA polymerase 'slips' while copying the repeated tracts because the DNA strands are denatured and displaced. The outcome of the replication error is the incorporation of more or fewer of the repeats in the promoter or coding regions of the affected genes.

The opacity proteins (Opa) of *N. gonorrhoeae*, which mediate adhesion, epithelial cell invasion, tissue tropism and host cell responses, undergo translational phase variation. A total of 11–12 *opa* loci in *N. gonorrhoeae* are dispersed throughout the genome, and a single bacterium can display a single Opa protein, multiple Opa proteins, or no Opa proteins. A repetitive 5'-CTCTT-3' sequence, termed the coding repeat, is present in the leader sequence-encoding region of each *opa* gene. The number of these coding repeats determines whether the coding sequence of a particular *opa* gene will be shifted in or out of frame relative to the ATG start codon. Each *opa* gene will be successfully translated into a functional Opa protein as long as 6, 9, or 12 of these coding repeats are present, which is referred to the phase 'on' position. If the number of coding repeats differs from a multiple of three, the gene is in the phase 'off' position, and an aberrant or truncated protein will be produced.

Phase variation by transcriptional slipped-strand mispairing occurs in the *opc* gene of *Neisseria meningitidis*, a pathogen that causes meningitis and sepsis. The *opc* gene encodes an outer membrane protein that facilitates attachment to the host epithelium. The promoter of the *opc* gene contains a repeated stretch of cytosines (poly(C) tract) where strand slippage can occur to produce a promoter of varying length. When there are 12 or 13 cytosine bases present, the gene is in the 'on' phase, transcription is initiated, and an abundance of Opc is produced. Transcription is also initiated when there is a tract of 11–14 cytosine bases in the *opc* promoter, although at a lower rate. However, when the cytosine bases number more than 15 or less than 10, the gene is in the 'off' phase because initiation of transcription does not occur and no Opc is produced. *T. pallidum* uses a similar strategy to regulate the expression of the outer membrane proteins encoded by the *tpr* gene family. The number of repeated tracts of guanosine bases (poly-G tract) encoded just upstream of the transcriptional start sites of the *tprE* gene and the *tprG/F* and *tprJ/I* operons control the transcription of these genes. Poly-G tracts with 8 or fewer encoded guanosine bases allows transcription to proceed, while longer poly-G tracts inhibit transcriptional initiation (Table 2).

Table 2 Mechanisms of phase variation and example organisms

Species	Gene	Surface antigen
<i>Gene inversion</i>		
<i>Escherichia coli</i>	<i>fimA</i>	Type I fimbriae
<i>Salmonella typhimurium</i>	<i>fljC</i> , <i>fljB</i>	Flagella
<i>Epigenetic modification</i>		
<i>Escherichia coli</i>	<i>papBA</i>	Pap pili
<i>Translational slipped-strand mispairing</i>		
<i>Neisseria gonorrhoeae</i>	<i>opa</i>	Opacity proteins
<i>Transcriptional slipped-strand mispairing</i>		
<i>Neisseria meningitidis</i>	<i>opc</i>	Outer membrane protein
<i>Treponema pallidum</i>	<i>tpr</i>	Putative outer membrane proteins

Importance of Antigenic Variation in Evasion of the Immune Response

The end goal of antigenic variation is to avoid clearance by the host immune response and promote transmission to new hosts. Phase variation, which as discussed can lead to antigenic variation, is also used to conserve energy by turning off expression of unneeded genes in response to environmental conditions (*e.g.*, expression of *E. coli* pili and flagella are reciprocal and pilin genes are only expressed when attachment to cell surfaces is required for colonization of the host). For most examples of antigenic variation, the systematic switching of a major surface protein from variant to variant helps the pathogen to avoid antibody-mediated clearance via complement activation, neutralization, or opsonization for engulfment by host phagocytes. Even small sequence changes in some surface-exposed proteins on the bacterial surface can prevent antibody recognition and binding to the surface of the bacteria. Avoidance of innate host factors by antigenic variation has also been shown, such as variation of lipopolysaccharide to avoid killing by cationic peptides. These examples are far fewer than examples of how antigenic variation allows escape from the adaptive immune response, the most striking of which is illustrated by blood-borne infections in which cyclic waves of bacteremia are followed by periods of recovery in patients as the host antibody response clears one variant, only to be challenged again as the population of the next variant grows in number. Ultimately, antigenic variation increases the duration of the infection, thus increasing the chance that the pathogen will be transmitted to a new host, whether by carriage by an arthropod vector to a new host in the case of species such as *B. burgdorferi* and *A. phagocytophilum* or by sexual transmission of the pathogen to a new host in the case of species such as *T. pallidum* and *N. gonorrhoeae*.

Beyond the evolutionary advantage of increasing the duration of the infection to increase the possibility of transmission to a new host, antigenic variations also allows for reinfection of the same host by the same pathogen as well as superinfection in which one host is persistently infected with several genetically distinct populations of the same pathogen. When protective immunity is not established during the initial infection, that host remains open to reinfection or superinfection. This lack of the ability to mount a sterilizing immune response effectively keeps the susceptible host population large and increases the chance of successful transmission and survival of the pathogen. Superinfection of the host also provides the additional advantage of possible genetic exchange of genes between genetically distinct populations of pathogens, which may contribute to the rapid rise of antibiotic resistance in some bacterial species.

Antimicrobial Susceptibility Testing[☆]

FC Tenover, Cepheid, Sunnyvale, CA, USA

© 2019 Elsevier Inc. All rights reserved.

Glossary

Antibiogram The antimicrobial susceptibility pattern of a bacterial isolate, indicating the antimicrobial agents to which the organism is susceptible and resistant.

Breakpoints The standardized criteria that enable disk diffusion and minimal inhibitory concentration (MIC) test results to be interpreted as susceptible, intermediate, or resistant.

Broth microdilution assays A minimal inhibitory concentration (MIC)-based susceptibility testing method in which a standardized inoculum of bacteria is transferred to all but one well of the 96-well tray containing growth media and doubling dilutions of the antimicrobial agents to be tested. After overnight incubation, the MICs of each antimicrobial agent are determined and the results are interpreted using standard guidelines (breakpoints). The last well in the plate serves as a sterility control for the broth growth medium.

Disk diffusion assay A susceptibility testing method in which paper disks, each saturated with a different antimicrobial agent, are placed on the surface of an agar medium that has been inoculated with a bacterial isolate. After overnight incubation, the zones of inhibition around the disks are measured and the results interpreted using standard guidelines (breakpoints).

Empiric therapy Antimicrobial therapy that is given to a patient with an infection before the biochemical identification of the organism and its standardized antimicrobial susceptibility patterns are known.

Hospital antibiogram An annual or semiannual report issued by the microbiology laboratory in a hospital that summarizes the percentage of organisms, usually by individual bacterial species, which are susceptible to various antimicrobial agents. These data are typically used to guide empiric therapy.

Minimal inhibitory concentration (MIC) The lowest concentration of an antimicrobial agent that prevents visible growth of a bacterial isolate on an agar plate or in a broth-based susceptibility testing assay.

This article is an update of F.C. Tenover, Antibiotic Susceptibility Testing, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 67–77.

Introduction

One of the major functions of a clinical microbiology laboratory is to test bacterial isolates recovered from patients with infections for susceptibility to a variety of antimicrobial agents. The results of the antimicrobial susceptibility testing are provided to physicians to guide their choice of antimicrobial therapy. The role of antimicrobial susceptibility testing of bacteria for guiding therapy for infectious diseases is becoming more and more important as resistance continues to spread among a wide variety of bacterial species, impacting both initial (empiric) and definitive therapy. Susceptibility testing (previously referred to as 'sensitivity testing') has long been one of the major functions of the clinical microbiology laboratory. In fact, it is not unusual to hear physicians in hospitals still request a 'C and S' (culture and sensitivity) for a variety of clinical specimens, including blood, urine, and sputum. The antimicrobial susceptibility data indicating which antimicrobial drugs are likely to be effective and those that are not are critical particularly in seriously ill patients, such as those with bloodstream infections, infections of heart valves (endocarditis), or meningitis. The value of the antimicrobial susceptibility data that are generated in a clinical microbiology laboratory goes beyond the individual patient. Cumulatively, the data are used to aid physicians in the selection of empiric therapy, that is, antimicrobial therapy for an infection in a patient before the biochemical identification of the organism and its standardized antimicrobial susceptibility patterns are known. The presentation of the cumulative data by year and usually by bacterial species is often referred to as the hospital's 'antibiogram.' The techniques by which the microbiology laboratory generates antimicrobial susceptibility testing data will be the subject of this article.

Testing for Antimicrobial Resistance in the Modern Era

Antimicrobial resistance among bacterial pathogens is no longer a rare event. Unfortunately, many of the novel resistance phenotypes that are emerging among bacterial species are not easily detected by the automated susceptibility testing methods frequently used in clinical laboratories today. Approximately 90% of clinical microbiology laboratories in the United States use an automated instrument to identify organisms to the species level and determine the susceptibility of that organism to various antimicrobial agents. The remaining laboratories typically use a disk diffusion method. The ability of the clinical laboratory to detect emerging resistance profiles is often directly related to the extra efforts that are expended to identify novel resistance mechanisms (Table 1). This includes inoculating agar plates containing a specific concentration of an antimicrobial agent to detect borderline resistance, molecular tests to detect specific genes encoding mechanisms of antimicrobial resistance or mutations associated with a resistance phenotype, or tests designed to detect inducible resistance that may otherwise go undetected. Thus, susceptibility testing has become a complex and often costly endeavor as the laboratory seeks to guide the physician in choosing the best antimicrobial agent to treat an infection.

Although antimicrobial resistant bacteria were for many years considered to be confined to intensive-care units of hospitals where antimicrobial agents are used most heavily, resistance to multiple antimicrobial agents (also called 'multidrug resistance' (MDR)) has emerged among strains of community-acquired pathogens, such as *Escherichia coli*, *Salmonella*, *Mycobacterium tuberculosis* (the causative agent of tuberculosis), and *Neisseria gonorrhoeae* (the causative agent of gonorrhea). To complicate matters further, resistant organisms that arise in the community, such as the novel community-associated methicillin-resistant *Staphylococcus aureus* (MRSA) strains, are now also spreading into healthcare settings. Thus, it is imperative that changes in resistance patterns of a wide range of bacterial pathogens be monitored continually to insure optimal treatment both of individual patients and for maintaining the efficacy of empiric therapy regimens.

Antimicrobial Susceptibility Testing Methods

It is rare for a clinical microbiology laboratory to use a single method to determine the antimicrobial susceptibility patterns of bacterial isolates, given the variety of bacterial species that need to be tested and their varying growth requirements. The two major

Table 1 Phenotypic screening and confirmation tests

Test name	Resistance phenotype detected	Organism groups
Aminoglycoside resistance, high level	Synergistic activity with ampicillin, penicillin, or vancomycin	Enterococci
Brain heart infusion vancomycin agar screen test	Vancomycin resistance	Staphylococci, enterococci
Cefoxitin disk test	<i>mecA</i> and <i>mecC</i> -mediated oxacillin resistance	Staphylococci
D-zone test	Inducible clindamycin resistance	Staphylococci, streptococci
Extended spectrum β -lactamase screening test	Penicillin and cephalosporin resistance	<i>Escherichia coli</i> , <i>Klebsiella</i> species, <i>Proteus mirabilis</i>
Carbapenem inactivation test (Modified Hodge Test)	Carbapenem resistance	Enterobacteriaceae
Oxacillin screen test	Penicillin susceptibility	<i>Streptococcus pneumoniae</i>

phenotypic methods of determining the susceptibility of a bacterial isolate to an antimicrobial agent are disk diffusion and minimal inhibitory concentration (MIC) testing. As noted above, in the United States, approximately 90% of susceptibility test results are produced using automated or semi-automated instruments that generate MIC data, often together with bacterial species identification, while the remainder of results are produced primarily by disk diffusion testing. Susceptibility testing results may be available in as little as 6–8 h for some antimicrobial agents, while others require a full 24 h to insure detection of resistance. However, clinical laboratories also utilize a series of screening and confirmation tests to detect subtle resistance mechanisms (those that produce low MIC values near the breakpoint that defines susceptibility) and insure the accuracy of antimicrobial susceptibility test reports (Table 1). More recently, molecular methods to detect antimicrobial resistance genes and mutations associated with resistance phenotypes have been introduced into clinical microbiology laboratories and are frequently used to test for resistant organisms directly in clinical samples, rather than be used on bacteria grown in culture.

Disk Diffusion

The disk diffusion method is among the most flexible susceptibility testing methods in terms of antimicrobial agents that can be tested. The method consists of placing paper disks saturated with antimicrobial agents on a lawn of bacteria seeded on the surface of an agar medium, incubating the plate overnight, and measuring the presence or absence of a zone of inhibition around the disks (Figure 1). Studies conducted at the University of Washington in the mid-1960s resulted in the technique often referred to as the 'Kirby–Bauer method,' which was published by Bauer and colleagues in 1966. This method standardized the variables of disk size, inoculum size, temperature, and time of incubation. Results are reported qualitatively as susceptible, intermediate, or resistant. The disk diffusion method described by Bauer and colleagues has been continually expanded and improved by the Clinical and Laboratory Standards Institute (CLSI) in the United States. Several other international societies (e.g., the European Union Committee for Antimicrobial Susceptibility Testing (EUCAST), and the British Society for Antimicrobial Chemotherapy) use similar techniques. Alternative disk-based methods, including the Roscoe NeoSensitabs and the Australian CDM method, are also used in some countries. Instruments that measure the zones of inhibition using cameras can speed the process of reading disk diffusion plates. These instruments can also transform the zone diameter readings into approximate MIC values.

MIC Testing

The goal of MIC testing is to provide a quantitative result (usually in $\mu\text{g ml}^{-1}$) along with a categorical interpretation (susceptible, intermediate, or resistant) that can guide antimicrobial therapy more precisely, particularly for infections in body sites where antimicrobial agents achieve lower concentrations than in serum (e.g., cerebrospinal fluid and bone). MIC testing can be performed

Figure 1 Disk diffusion test for *Staphylococcus aureus*. No zone of growth inhibition is observed around the ampicillin (AM) disk. Photo courtesy of Janet Hindler.

by one of several methods including agar dilution, broth microdilution, agar gradient dilution, or by one of several automated or semiautomated methods. Quantitative MIC results are also useful when long-term therapy is required, as for bacterial endocarditis.

Agar dilution

The agar dilution method involves preparing a series of agar plates containing the antimicrobial agent to be tested in increasing concentrations, usually in doubling dilutions (i.e., 1, 2, 4, 8, 16, 32 $\mu\text{g ml}^{-1}$, etc.). A suspension of the organism to be tested is prepared to equal the turbidity of a 0.5 McFarland standard ($\sim 1 \times 10^8$ colony forming units (CFU) ml^{-1}), and 1–5 μl of this suspension is placed on each of the series of plates with increasing concentrations of the antimicrobial agent using a replicator device (final inoculum is $\sim 5 \times 10^4$ CFU/spot). Thirty different bacterial isolates (plus quality control organisms) can be tested simultaneously on each agar plate. Nonfastidious organisms are incubated at 35 °C for 16–18 h usually in ambient air, while fastidious organisms, such as *Streptococcus pneumoniae*, are tested on blood-containing media, incubated from 18 to 24 h, typically in a CO_2 -enriched atmosphere. The agar dilution method, while laborious due to the time required to prepare each set of agar plates for each antimicrobial agent to be tested, is often cost-effective for laboratories that test large numbers of bacterial isolates against a limited set of antimicrobial agents. The testing medium is usually Mueller–Hinton agar for nonfastidious organisms and Mueller–Hinton agar containing 5% sheep blood for fastidious organisms. The exceptions are *Haemophilus influenzae* isolates, which require HTM (CLSI) or MH-F (EUCAST), and *N. gonorrhoeae*, which requires GC medium.

Broth microdilution

Broth microdilution is the standard method used in most reference laboratories in the United States and abroad. The method typically tests twofold dilutions of multiple antimicrobial agents in 96-well disposable plastic trays (Figure 2). The test medium is typically cation-adjusted Mueller–Hinton broth, or for fastidious organisms, cation-adjusted Mueller–Hinton broth containing 5% lysed horse blood. A suspension of the organism to be tested is prepared in saline or Mueller–Hinton broth to the turbidity of a 0.5 McFarland standard ($\sim 1 \times 10^8$ CFU ml^{-1}). The suspension is diluted 1:20 in saline, and 1–5 μl of this suspension is transferred to all but one well of the 96-well tray containing doubling dilutions of the antimicrobial agents to be tested (usually between 8 and 12 antimicrobial agents per tray) using a disposable plastic inoculator (the remaining well is a broth sterility control). The final inoculum size is 5×10^5 CFU ml^{-1} or 5×10^4 CFU/well.

Automated susceptibility testing methods

A series of commercially available automated and semiautomated methods are used in clinical microbiology laboratories to test and report the results of antimicrobial susceptibility tests. Most of the methods combine bacterial identification and susceptibility testing reagents in a single panel or card to enhance the speed with which antimicrobial susceptibility testing results can be reported to physicians. Many systems also incorporate software programs to interpret the results and prepare reports that can be linked readily to laboratory information systems, which in turn deliver the results to the patient's medical record. The goal of the automated methods is to reduce the time necessary to produce accurate identification and susceptibility test results. Indeed, results may be available for some bacterial species in as little as 6 h, versus the 16–24 h often required for disk diffusion testing or standard MIC tests. For staphylococci, the results of oxacillin and vancomycin tests often require prolonged incubation times (up to 24 h) to

Figure 2 Minimal inhibitory concentration (MIC) test with *Staphylococcus aureus*. The first well where complete inhibition of growth is observed is considered the MIC for that antimicrobial agent. The lowest concentrations of the antimicrobial agents are on the top of the plate and the concentrations of the drugs increase in doubling dilutions (1, 2, 4, 8 $\mu\text{g ml}^{-1}$, and so on) toward the bottom of the plate (there are 12 drugs tested in this plate (columns 1, 2, 3, . . . each are different antimicrobial agents)). The pink well is the growth control. Photo courtesy of Janet Hindler.

achieve accurate results. Some software programs employ 'expert systems' to enhance reporting by recognizing and flagging unusual results, such as ampicillin-susceptible *Klebsiella pneumoniae*, where the bacterial identification and susceptibility pattern are conflicting with typical results for wild-type *K. pneumoniae* populations, or less common results, such as carbapenem-resistant Enterobacteriaceae or vancomycin-resistant *S. aureus* isolates.

Overall, automated systems work well, although they have traditionally shown problems with certain resistance phenotypes, including oxacillin-resistant *S. aureus* isolates and *Pseudomonas aeruginosa* isolates that are resistant to β -lactam agents, such as piperacillin. Inducible resistance, such as clindamycin resistance caused by *erm*-type genes in staphylococci, is difficult to detect in automated systems, although some systems now incorporate wells containing both erythromycin and clindamycin to detect this phenotype. Finally, the detection of resistance due to induction of β -lactamases present among some strains of Enterobacteriaceae, and the related problem of detection of resistance to third-generation cephalosporins due to extended-spectrum β -lactamases (ESBLs), has been addressed in many of the automated systems by use of low concentrations of β -lactams as screening tests. When positive, these tests indicate to the user that additional testing outside of the automated system may be necessary to achieve accurate results.

Agar gradient dilution

Agar gradient dilution allows the generation of MIC data in a testing format similar to that of disk diffusion testing (Figure 3). The antimicrobial agent is microencapsulated on the back of a plastic strip, and when placed on the surface of an agar plate, the antimicrobial agent diffuses from the strip into the agar medium in a rapid and predictable fashion forming a gradient. Agar gradient strips, which are available from at least two commercial sources, evaluate the inhibitory potential of a single antimicrobial agent over a large range of concentrations (e.g., 0.03 – $256 \mu\text{g ml}^{-1}$). Several test strips, each containing a different antimicrobial agent, can be arranged on a single agar plate. The agar gradient method is particularly useful for testing fastidious microorganisms such as campylobacters, pneumococci, and anaerobic bacteria, where only a limited number of antimicrobial agents need to be tested.

Molecular Diagnostic Testing Methods

Over the last several years, a series of molecular assays using nucleic acid amplification methods, microarrays, line probes, and several other methods have been developed to detect antimicrobial resistance genes and mutations associated with resistance phenotypes. The most commonly used molecular tests for antimicrobial resistance are real-time polymerase chain reaction (PCR) assays to detect the *mecA* methicillin resistance gene associated with MRSA isolates directly in clinical samples (including positive blood culture bottles, wounds specimens, and nasal swabs for surveillance), often in <2 h. Several commercial methods for identifying gram-positive cocci in blood culture bottles also test for the presence of the vancomycin resistance genes, *vanA* and *vanB*, among enterococci, while other assays test for the presence of the *bla*_{KPC} carbapenem resistance gene in gram-negative

Figure 3 Agar gradient diffusion (Etest method is pictured) analysis of *Staphylococcus aureus* showing results for vancomycin (VA) and teicoplanin (TP), two glycopeptides drugs. The MICs are read off of the strip where the bottom portion of the ellipse intersects with the strip (see white arrows). (VA MIC = $1 \mu\text{g ml}^{-1}$, TP MIC = $1.5 \mu\text{g ml}^{-1}$).

organisms causing sepsis. PCR assays using molecular beacon technology and line probe assay have been developed to detect mutations in the ribosomal RNA polymerase gene *rpoB* associated with rifampin resistance in *M. tuberculosis*. Rifampin resistance is frequently a marker of multidrug-resistance in *M. tuberculosis*. The PCR assays can be performed directly on expectorated sputum samples or concentrated pellets prepared for mycobacterial culture, produce results in <2 h, and are now used in over 100 countries worldwide, including many that have been designated as high burden, developing countries (HBDC) by the World Health Organization. Line probes that utilize reverse hybridization also can be used to assess both rifampin and isoniazid resistance.

Interpretive Guidelines

Once a disk diffusion zone of inhibition has been measured or an MIC for an antimicrobial agent has been determined, and the microbiologist has affirmed that the quality control results indicate that the testing system has performed appropriately, the results of the susceptibility tests have to be interpreted. For most antimicrobial agents, the results transmitted to the patient's chart will be reported as either 'susceptible,' 'intermediate,' or 'resistant.' If an MIC method was used, the results transmitted may include the quantitative MIC results, usually reported in $\mu\text{g ml}^{-1}$, as well (see Table 2 for an example). However, for some antimicrobial agents, such as linezolid when testing staphylococci, the results transmitted will be either 'susceptible' or 'nonsusceptible.' At the time the drug was approved for use by the United States Food and Drug Administration, and when interpretive criteria (i.e., breakpoints) were established by the CLSI, there were inadequate numbers of resistant strains available with associated clinical outcome data on which to establish intermediate and resistant breakpoints. The lack of intermediate and resistant breakpoints often poses a challenge for the automated methods which, depending on the system, will either leave the interpretation field blank for a nonsusceptible result, or place an 'N' or 'NS' (for nonsusceptible), or an 'NI' (for noninterpretable) in the interpretation field – a result that may be confusing to the physician reading the laboratory report. Some microbiology laboratories will override these 'NS' results and report them as resistant to avoid confusing physicians, even though technically, resistance has not been defined. Recently, a new interpretive category called 'susceptible dose dependent' (SDD) was introduced by CLSI for reporting results for cefepime for bacterial infections. Although this category has been used for reporting results for antifungal susceptibility testing for several years, its application for cefepime results for bacterial infections is novel. It is meant to bring clarity to the intermediate category by indicating to the physician that the organism causing the infection may still respond to cefepime if high doses of the drug are used.

The categorical interpretations used for disk diffusion and MIC test results are developed by a number of organizations around the world. In the United States, this is done initially by the FDA, with follow up criteria established by CLSI (the two sets of criteria may or may not be the same). The reference disk diffusion method for the United States is defined in the CLSI M2 document (i.e., Performance Standards for Antimicrobial Disk Susceptibility Tests). The M2 document is revised every 3 years. The next version of the M2 document (M2-A12) will be published in January 2015. The agar and broth dilution reference (MIC) methods are described in the CLSI M7 document (Methods for Dilution Antimicrobial Susceptibility Tests for bacteria that grow aerobically). The next version of the M7 document (M7-A10) will be published in January 2015. A separate document containing the interpretive criteria for both disk diffusion and MIC testing, quality control ranges, and methods for preparing and diluting antimicrobial agents, is published each year in January (the M100 series). A separate document outlining testing methods and interpretive criteria for fastidious bacteria and organisms that are isolated only infrequently in clinical laboratories, CLSI document M45 is also available. Similar documents describing susceptibility testing methods and interpretive criteria are published by the EUCAST (<http://www.srga.org/>), the British Society for Antimicrobial Chemotherapy (<http://www.bsac.org.uk/>), and other international organizations.

Resistance Phenotypes That Require Specialized Testing

Penicillin-Resistant Pneumococci

For many years, before the introduction of the agar gradient diffusion method and commercially available MIC panels for fastidious organisms, performing MIC tests on isolates of *S. pneumoniae* was too difficult and costly for many clinical laboratories, particularly

Table 2 Antimicrobial susceptibility test results for an *Escherichia coli* isolate from a blood culture

Antimicrobial agent	Minimal inhibitory concentration ($\mu\text{g ml}^{-1}$)	Interpretation
Ampicillin	>128	Resistant
Cefazolin	>32	Resistant
Cefotaxime	1	Susceptible
Ciprofloxacin	2	Intermediate
Gentamicin	1	Susceptible

those in developing countries. Yet, even as early as 1977, penicillin resistance was emerging around the world and multiply drug-resistant pneumococci were reported in South Africa. One simple test for identifying strains with the potential for penicillin resistance, which is still used in many laboratories today, is the oxacillin disk screening test. A 1- μ g oxacillin disk is placed on a Mueller–Hinton agar plate containing 5% sheep blood that has been inoculated with the strain of *S. pneumoniae* to be tested. A zone of growth inhibition of ≥ 20 mm around the oxacillin disk indicates that the *S. pneumoniae* strain is susceptible to penicillin. If the zone of inhibition around the oxacillin disk is ≤ 19 mm, this indicates that the organism has undergone some change in its penicillin-binding proteins; however, the organism could still be penicillin-susceptible. Thus, an MIC test is required to differentiate penicillin-susceptible from penicillin-resistant organisms if the zone of inhibition is ≤ 19 mm. *S. pneumoniae* strains that are susceptible to penicillin are considered susceptible to all β -lactam agents.

Oxacillin Resistance Among Staphylococci

Although the term MRSA is thoroughly entrenched in the medical literature, it is often oxacillin that is tested in lieu of methicillin due to its greater stability during testing procedures. Oxacillin MICs are still determined in many commercial AST systems. However, more recently, the cephamycin cefoxitin has replaced oxacillin in both disk diffusion and MIC testing. Cefoxitin is a better predictor of strains of staphylococci that carry the *mecA* and *mecC* methicillin resistance genes. Even so, detection of oxacillin resistance in staphylococci can be difficult because oxacillin-resistant strains, particularly of *S. aureus*, grow more slowly than susceptible strains and often show heteroresistance, that is, only a portion of the population of organisms (i.e., 1 in every 100 000 cells) show oxacillin resistance. Incubating staphylococci at 35 °C instead of 37 °C, adding 2% NaCl to the broth testing medium, and incubating the test for a full 24 h improves the detection of oxacillin-resistant strains. For disk diffusion testing, CLSI recommends using a 30- μ g cefoxitin disk instead of a 1- μ g oxacillin disk to predict the presence of *mecA* or *mecC* among both *S. aureus* and coagulase-negative staphylococcal isolates. The cefoxitin disk diffusion test can be read in 16–18 h and shows levels of sensitivity and specificity that are higher than those of the oxacillin disk, particularly for testing coagulase-negative staphylococci.

Extended-Spectrum β -Lactamase Producing Enterobacteriaceae

Among the Enterobacteriaceae, a major susceptibility testing challenge is detecting the presence of ESBLs. These β -lactamases, which are typically the result of mutations in *bla*_{TEM}, *bla*_{SHV} or *bla*_{CTX-M} β -lactamase genes, have a much wider spectrum of activity than the wild-type (unmutated) β -lactamase and can hydrolyze monobactams (such as aztreonam), most third-generation cephalosporins (such as cefotaxime, ceftriaxone, and ceftazidime) and, in some cases, even fourth-generation cephalosporins (such as cefepime and ceftipime). Since the ESBLs do not hydrolyze all of the extended-spectrum cephalosporins at similar rates, some organisms may show resistance to one or two third-generation cephalosporins but susceptibility to others in laboratory tests. Clinical data, however, show that patients infected with ESBL-producing organisms will fail therapy when treated with any of the cephalosporin drugs even if the organisms appear susceptible *in vitro*. The dilemma was what to do with an organism that is resistant to one or two third-generation cephalosporins, but susceptible to other cephalosporins. For almost a decade the answer was to determine if the organism was an ESBL producer, and if so, to use this information to modify the results for most of the beta-lactam drugs (except carbapenems) to non-susceptible (either I or R depending on laboratory policy). Isolates of *Escherichia coli*, *K. pneumoniae*, and *Proteus mirabilis* that were suspected ESBL producers were tested against cefotaxime and ceftazidime, either by disk diffusion or by a broth microdilution assay, in the presence and absence of clavulanic acid – a β -lactamase inhibitor. If the zones of inhibition increase by 5 mm or more in the presence of clavulanic acid, or the MICs decrease by three or more doubling dilutions in the presence of clavulanic acid when compared to the results in the absence of clavulanic acid, the organism was presumed to harbor an ESBL and the results for all penicillins, cephalosporins, and aztreonam were reported as resistant, since those infections will not respond to those drugs. The reports for other antimicrobial agents, including β -lactam/ β -lactamase inhibitor combinations (e.g., piperacillin-tazobactam) and cephamycins (cefotetan and cefoxitin) are not affected by ESBL testing and the susceptible or intermediate results obtained by routine testing were not modified. The β -lactam/ β -lactamase inhibitor combinations were presumed to still be effective against some ESBL-producing strains. Similar strategies to identify plasmid-mediated AmpC β -lactamases using boronic acid were described, but were not incorporated into CLSI documents and were not routinely used in the United States.

More recently, this approach of determining the presence of ESBLs to modify susceptibility testing results has fallen on disfavor. The additional testing delays the time it takes to finalize AST results and the method often suffers from technical problems. In lieu of additional testing, both CLSI and EUCAST lowered the susceptibility breakpoints for most cephalosporins making them more sensitive for the detection of ESBL and AmpC producing organisms. ESBL testing is now used primarily for epidemiologic purposes. Although this approach has its critics, it is now in use globally.

Detecting Carbapenemase-Producing Gram-Negative Bacilli

The carbapenems, that is, doripenem, ertapenem, imipenem, and meropenem, are highly potent β -lactam agents that are often held in reserve for the sickest patients in the hospital with the most difficult to treat Gram-negative organisms. Carbapenems often are

Figure 4 A carbapenem inactivation assay using imipenem (IMI) and ertapenem (ERT) disks. The growth of the indicator organism toward the disk at the top of the zone of inhibition around the streak of growth indicates a positive test (arrow). The lack of indentation of the zone of inhibition on the bottom of the zone is a negative test.

active even against bacteria that contain ESBLs or AmpC β -lactamases. Organisms, such as *K. pneumoniae*, that are carbapenem-resistant are often resistant to all available antimicrobial agents. However, as with the ESBLs, not all organisms that contain carbapenemases, such as the KPC (*Klebsiella pneumoniae* carbapenemase), VIM (Verona integron mediated β -lactamase), or NDM (New Delhi metallo β -lactamase), are detected as resistant to each of the carbapenems by automated susceptibility testing methods. Thus, additional *in vitro* assays were often required to identify those stealth resistance mechanisms. The most common test was a carbapenem inactivation assay in which a sensitive indicator strain of *E. coli* was inoculated onto an agar plate and one or more disks containing carbapenem drugs were placed on the plate (Figure 4). The organism to be investigated was then streaked from the disk out to the edge of the agar plate. A control organism that does not inactivate carbapenems is often streaked on the opposite side of the disk. If a carbapenemase type β -lactamase was present, the drug was inactivated and the susceptible *E. coli* grew in from the edge of the zone of inhibition toward the disk. If the test was positive, all carbapenem results were reported as resistant.

As with the ESBLs, detecting carbapenemase-producing organisms using the Modified Hodge Test was not always effective as some organisms, especially those containing an NDM carbapenemase, escaped detection. False positive test results, often with AmpC containing organisms, coupled with tests that yielded indeterminate results further undermined the utility of the assay. Thus, CLSI and EUCAST adopted the strategy of establishing lower breakpoints for the carbapenem drugs to enhance detection of resistant strains, especially those that clustered at the susceptible/intermediate breakpoints. This strategy has not been met with universal acceptance, although it does appear to be increasing the accuracy of results for carbapenem testing globally.

Detecting Inducible Clindamycin Resistance Among Gram-Positive Cocci

Staphylococci and streptococci that are resistant to erythromycin (a macrolide class drug) are often also resistant to clindamycin (a lincosamide drug) because resistance to both drugs can be mediated by the same mechanism, that is, methylation of the 50S bacterial ribosome. This is referred to as the MLS_B-resistance phenotype (for macrolide–lincosamide–streptogramin_B) and is mediated by one of the *erm* family of resistance genes. However, some isolates of staphylococci and streptococci that are erythromycin-resistant due to carriage of an *erm* gene, appear clindamycin-susceptible in laboratory tests because the *erm* gene is inducible and clindamycin itself is not a good inducer (i.e., the gene is not activated during the time it takes to complete the susceptibility test). Because spontaneous mutations can occur in the *erm* gene during clindamycin therapy, which lead to high-level clindamycin resistance and thus treatment failure, it is important to identify organisms that contain an inducible *erm* gene. Such isolates must be differentiated from other isolates of staphylococci and streptococci that contain an efflux-type macrolide resistance gene, which does not mediate clindamycin resistance, and can be treated successfully with clindamycin. Examples of erythromycin efflux mechanisms that do not mediate clindamycin resistance are *msrA* (in staphylococci) or *mefA* (in streptococci). Thus, for strains of staphylococci or streptococci that show an erythromycin-resistant, clindamycin-susceptible phenotype, it is important to differentiate between those strains that carry an inducible *erm* gene (which may cause clindamycin treatment failure) and those that harbor an efflux gene (which will not result in clindamycin failure). The D-zone test, which is a disk diffusion-based assay, uses a 15- μ g erythromycin disk that is placed 15–26 mm away from a 2- μ g clindamycin disk on an agar plate that has been inoculated with the test organism. Blunting of the zone of inhibition between the erythromycin and clindamycin disks (which forms a ‘D’ shape) indicates the presence of an inducible *erm* gene (a positive test) (Figure 5). A circular zone of inhibition (normal zone) indicates a negative test. If the D-zone test is positive, the results for clindamycin are reported as resistant to avoid a potential treatment failure.

Inactivation of carbapenem drug

Figure 5 Positive D-zone test showing blunting of the zone of inhibition between the erythromycin (E) and clindamycin (CC) disks. Photo courtesy of Janet Hindler.

High-Level Aminoglycoside Resistance Among Enterococci

Serious enterococcal infections, such as endocarditis, are usually treated with a combination of antimicrobial agents that are synergistic (i.e., have enhanced killing activity when used in combination), such as a cell wall-active agent and an aminoglycoside. To determine whether there is likely to be synergy between the cell wall-active agent (usually ampicillin, penicillin, or vancomycin) and the aminoglycoside (i.e., gentamicin or streptomycin) special disk diffusion and MIC tests to detect high-level aminoglycoside resistance have been established by CLSI. The presence of high-level resistance to either aminoglycoside will negate the likelihood of synergistic activity with ampicillin, penicillin, or vancomycin, which is important information for the physician treating the patient.

Detecting Resistance to Vancomycin Among Staphylococci

Vancomycin is a member of the glycopeptide class of drugs, which are large molecules that diffuse poorly through agar media. Thus, disk diffusion testing with vancomycin and other glycopeptides often does not discriminate very well between susceptible isolates and those with intermediate or reduced susceptibility to the glycopeptides tested, such as the vancomycin-intermediate *S. aureus* (VISA) strains. While detection of *S. aureus* strains with high-level vancomycin resistance (i.e., vancomycin MICs $>32 \mu\text{g ml}^{-1}$), such as those rare strains that contain the *vanA* resistance gene from enterococci, can still be detected as resistant by disk diffusion, VISA isolates cannot be distinguished from vancomycin-susceptible *S. aureus* isolates using the disk diffusion method. Thus, laboratories often inoculate 10^6 CFU of the staphylococcal strain to be tested onto a Brain Heart Infusion agar plate containing $6 \mu\text{g ml}^{-1}$ of vancomycin to check for reduced susceptibility to vancomycin. Those organisms with reduced susceptibility to vancomycin will grow within 24 h. This technique is very sensitive ($>99\%$) for detecting isolates for which the vancomycin MICs are $8 \mu\text{g ml}^{-1}$ or higher, but only about 75% sensitive for isolates for which the vancomycin MICs are $4 \mu\text{g ml}^{-1}$.

Fluoroquinolone Resistance in *Salmonella Typhi* and Other Extraintestinal *Salmonella* Infections

Clinical failures have been reported when treating *S. typhi* infections, that is, typhoid fever, and other extraintestinal salmonella infections, with fluoroquinolones when the fluoroquinolone MICs (such as for levofloxacin) are in the upper end of the susceptible range (i.e., MICs of $0.25\text{--}1 \mu\text{g ml}^{-1}$; the levofloxacin susceptible breakpoint is $<2 \mu\text{g ml}^{-1}$). Interestingly, such salmonella strains usually show nalidixic acid MICs that are resistant (MIC $>16 \mu\text{g ml}^{-1}$), so a nalidixic acid disk diffusion test was used to try and identify low level resistant strains. However, not all fluoroquinolone resistance was detected by this method, so lower ciprofloxacin breakpoints were instituted by CLSI.

Molecular Tests for Identification of Patients Colonized with Resistant Bacteria

Rapid tests to identify patients colonized with MRSA

Screening patients being admitted to hospitals or other healthcare institutions for nasal colonization with MRSA is becoming widespread in the United States and elsewhere around the world as part of enhanced infection control programs. Screening for MRSA can be accomplished by plating material from nasal swabs directly on selective agar media that inhibit the growth of most organisms, while allowing MRSA to produce clearly identifiable colonies. However, this often requires 18–72 h depending on the medium used, whether an overnight broth enrichment step is included, and the number of confirmatory tests undertaken by the laboratory to prove that the organism growing on the agar is MRSA. A more rapid approach uses molecular amplification tests, such

as PCR, that simultaneously target the *mecA* gene and a chromosomal DNA sequence that is unique to *S. aureus*, thereby linking the resistance gene specifically to the *S. aureus* strain that carries it. PCR-based assays for MRSA detection often can be completed in <2 h from the time the nasal swab specimen arrives in the laboratory, versus the 18–72 h often required to complete an agar-based identification test. Amplification-based assays are more expensive to perform but the rapid turnaround time can be important when trying to control the spread of MRSA in a hospital setting.

Molecular assays for detecting colonization with VRE and carbapenem-resistant organisms (CRO)

Molecular assays for VRE and CROs to identify colonized patients to aid in infection control efforts have been instituted in a variety of healthcare settings. These assays, which target both *vanA* and *vanB* vancomycin resistance genes, or multiple carbapenem resistance genes including *bla_{KPC}*, *bla_{VIM}*, *bla_{NDM}*, *bla_{OXA48}*, and *bla_{IMP}*, are often more sensitive than conventional agar screening media for detecting resistant organisms, with results available often in <1 h. While there is a high correlation between the results of molecular assays for *vanA* in perirectal samples and positive cultures for VRE containing *vanA*, the correlation of molecular assays and cultures for *vanB* is lower, that is, several *vanB*-positive samples have negative cultures for enterococci containing the *vanB* gene. This probably reflects the fact that organisms in bowel flora other than enterococci, such as *Clostridium* species, can harbor the *vanB* resistance determinant. Correlation of results for detection of CROs by culture and molecular methods, however, is very high.

Conclusion

As antimicrobial resistance becomes more widespread among bacterial species, the role of the clinical laboratory to produce accurate and timely antimicrobial susceptibility test results becomes more critical to the physician who has the responsibility of treating the infected patient and controlling the spread of the disease to others.

Glossary

Alanine aminotransferase An enzyme found in the liver and blood serum, the concentration of which is often elevated in cases of liver damage.

Antiretroviral agent Any drug used in treating patients with human immunodeficiency virus (HIV) infection.

Antiviral resistance The developed resistance of a virus to a specific drug.

Bilirubin A greenish compound formed in the liver from the degradation of the hemoglobin from degraded red blood cells.

Bioavailability The property of a drug to be absorbed and distributed within the body in a way that preserves its useful characteristics; for example, it is not broken down, inactivated, or made insoluble.

Chemoprophylaxis Preventive treatment with chemical agents such as drugs.

Codon A triplet of three consecutive nucleotide components in the linear genetic code in DNA or messenger RNA, which designates a specific amino acid in the linear sequence of a protein molecule.

Creatinine An end product of energy metabolism found in the blood in uniform concentration, which is excreted by the kidney at a constant rate. Alterations of this rate are considered an indication of kidney malfunction.

Cytokine One of a variety of proteins which has a regulatory effect on a cell.

Drug resistance Decreased susceptibility to antiviral usually due to changes in the amino acid residues of target enzyme. For example, a substitution of valine for methionine at residue 184 of the reverse transcriptase enzyme of HIV confers resistance to lamivudine (M184V mutation, see Table 1 for letter codes of amino acids).

EC₅₀ Concentration of a drug that produces a 50% effect, for example, in virus yield.

Hemagglutinin Specific glycoprotein molecules on the surface of some viruses, which have the property of binding to the surface of the red blood cells of some animal species. Because there are multiple binding sites, one virus can bind to two red cells causing them to clump (agglutinate).

Hepatotoxicity Liver toxicity.

Interferon Any group of glycoproteins with antiviral activity.

Lipoatrophy Redistribution/accumulation of body fat including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and 'cushingoid appearance' observed in some patients receiving antiviral agents for HIV treatment.

Maintenance therapy Drug treatment given for a long time to maintain its effect after the condition has been controlled or to prevent recurrence.

Monotherapy Treatment with a single drug, contrasted with combination therapies with more than one drug at the same time.

Mutations Changes to the base pair sequence of the genetic material of an organism.

Nephrolithiasis The presence of kidney stones.

Nephrotoxicity Kidney toxicity.

Neuraminidase An enzyme, present on the surface of some viruses, which catalyzes the cleavage of a sugar derivative called neuraminic acid.

Peptidomimetic A molecule having properties similar to those of a peptide or short protein.

Pharmacokinetic Refers to the rates and efficiency of uptake, distribution, and disposition of a drug in the body.

Phase III The final stage in testing of a new drug, after determination of its safety and effectiveness, in which it is tested on a broad range, and large population of patients for comparison to existing treatments and to test for rare complications.

Placebo An agent used as a 'control' in tests of drugs. The placebo is an agent without the specific effects of the drug under test and is used to determine to what extent any observed effects of the drug are due to psychological effects or expectations. It is usually given to some patients while the test drug is given to others, but neither group knows which agent it is receiving (the so-called 'blind' design).

Prodrug A drug that is given in a form that is inactive and must be metabolized in the body to the active form.

Prophylaxis Prevention.

This article is an update of E. Paintsil, Yung-Chi Cheng, Antiviral Agents, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 223–257.

Protease An enzyme that catalyzes the cleavage of proteins. In the case of HIV, a virus-specific protease is needed to cleave some of the virus coat proteins into their final, active form.

Protease inhibitor A substance that inhibits the action of protease enzyme.

Replication cycle The series of steps that a virus or cell goes through to multiply.

Shingles Eruptive rash, usually in a girdle (L. cingulus; hence 'shingles') distribution on the trunk, resulting from infection with varicella zoster virus.

T_{1/2} The time for reduction of some observed quantity, for example, the blood concentration of a drug, by 50%.

Teratogenesis Production of fetal abnormalities by some agent.

Therapeutic index The numerical ratio of the concentration needed to achieve a desired effect in 50% of the patients and the concentration that produces unacceptable toxicity in 50% of the patients.

Thymidine kinase An enzyme that catalyzes the transfer of a phosphoryl group from a donor such as adenosine triphosphate to the sugar (deoxyribose) component of the thymidine molecule, a building block of DNA.

Viremia The presence of virus in the bloodstream.

Virion A complete virus, including the coat and nucleic acid core.

Abbreviations

ALT	Alanine aminotransferase
CMV	Cytomegalovirus
CNS	Central nervous system disease
CoV	Coronavirus
CPK	Creatinine phosphokinase
CSF	Cerebrospinal fluid
CYP	Cytochrome P450
dATP	Deoxyadenosine triphosphate
dGTP	Deoxyguanosine triphosphate
EBV	Epstein-Barr virus
FDA	Food and Drug Administration
FEV1	Reduced forced expiratory volume
HAART	Highly active antiretroviral therapy
HBeAg	Hepatitis B e antigen
HBV	Hepatitis B virus
HCV	Hepatitis C virus
HHV-6	Human herpes virus-6
HHV-7	Human herpes virus-7
HHV-8	Human herpes virus-8
HIV	Human immunodeficiency virus
HPMPC	(S)-1-(3-hydroxy-2-phosphonylmethoxypropyl) cytosine
HPV	Human papillomavirus
HSE	Herpes simplex encephalitis
HSV	Herpes simplex virus
IFNs	Interferons
MNR	Multinucleoside resistance
NA	Neuraminidase
NAMs	Nucleoside-analog-associated mutations
NK	Natural killer
PEG	Polyethylene glycol
Pgp	P-glycoprotein
RSV	Respiratory syncytial virus
SARS	Severe acute respiratory syndrome
SEM	Skin, eye, or mouth
SPAG	Small-particle aerosol generator
TAMs	Thymidine analog resistance mutations
TK	Thymidine kinases
UGT	UDP-glucuronosyl transferase
VZV	varicella zoster virus

Defining Statement

Antiviral agents are drugs approved in the USA by the Food and Drug Administration (FDA) for the treatment or control of viral infections. They target stages in the viral life cycle. An ideal antiviral agent should be effective against both actively replicating and latent viruses; however, most of the available antiviral agents are effective against only replicating viruses.

Introduction

Antiviral agents are drugs approved in the USA by the Food and Drug Administration (FDA) for the treatment or control of viral infections. The development of antiviral agents is not trivial as viral replication is intricately linked with the host cell that any antiviral drug that interferes even to a lesser extent with host cell factors may be toxic to the host depending on the duration and dosage used. Available antiviral agents mainly target stages in the viral life cycle. The target stages in the viral life cycle are; viral attachment to host cell, uncoating, synthesis of viral mRNA, translation of mRNA, replication of viral RNA and DNA, maturation of new viral proteins, budding, release of newly synthesized virus, and free virus in body fluids. Antiviral agents used to treat viral diseases are currently limited, and at least half of the available agents are for the treatment of human immunodeficiency virus (HIV) infections. The others are used for the management of herpes simplex virus (HSV), varicella zoster virus (VZV), cytomegalovirus (CMV), hepatitis B virus (HBV), hepatitis C virus (HCV), respiratory syncytial virus (RSV), human papillomavirus (HPV), and influenza virus-related diseases.

Viruses could stay in the cells in an episomal form, or are incorporated into host chromosomal DNA without engaging in active viral replication (i.e., viral latency state). An ideal antiviral agent should be effective against both actively replicating and latent viruses; however, most of the available antiviral agents are only effective against replicating viruses. The goals for treating acute viral infections in immunocompetent patients are to reduce the severity of the illness and its complications and to decrease the rate of transmission of the virus. The therapeutic index, or ratio of efficacy to toxicity, must be extremely high in order for the therapy to be acceptable. For chronic viral infections, the goal is to prevent viral damage to visceral organs, and therefore efficacy becomes paramount. Antiviral agents can be used for prophylaxis, suppression, preemptive therapy, or treatment of overt disease. Two important factors that can limit the utility of antiviral drugs are toxicity and the development of resistance to the antiviral agent by the virus. In addition, host phenotypic behaviors toward antiviral drugs because of either genomic or epigenetic factors could limit the efficacy of an antiviral agent in an individual. This article summarizes the most relevant pharmacologic and clinical properties of the available antiviral agents.

Therapeutics for Herpesvirus Infections

There are eight members of the human herpesviridae family: HSV-1, HSV-2, VZV, Epstein–Barr virus (EBV), CMV, human herpes virus-6 (HHV-6), human herpes virus-7 (HHV-7), and human herpes virus-8 (HHV-8). The hallmark of the herpesviruses is their ability to establish latency within the neuronal ganglia of the nervous system or cells of the immune system and reactivate during periods of stress, trauma, or immune suppression.

Acyclovir

Chemistry, mechanism of action, and antiviral activity

Acyclovir [9-(2-hydroxyethoxymethyl) guanine] is a synthetic acyclic purine nucleoside analogue that lacks the 3'-hydroxyl group of nucleosides. Acyclovir is phosphorylated to the active triphosphate metabolite that inhibits viral DNA synthesis (Figure 1). Viral encoded thymidine kinases (TK), present in only herpesvirus-infected cells, catalyze the phosphorylation to acyclovir monophosphate. Host cell TK or other kinases cannot phosphorylate acyclovir to its monophosphate metabolite efficiently. Acyclovir is highly selective for cells engaged in active viral replication and does not affect noninfected cells. The monophosphate is subsequently phosphorylated to the di-, and triphosphate by cellular kinases, resulting in acyclovir triphosphate concentrations much higher in HSV-infected than in uninfected cells. Acyclovir triphosphate inhibits viral DNA synthesis by competing with deoxyguanosine triphosphate (dGTP) as a substrate for viral DNA polymerase, as illustrated in Figure 1. Since acyclovir triphosphate lacks the

Figure 1 The mechanism of action of acyclovir: (a) activation; (b) inhibition of DNA synthesis and chain termination.

3'-hydroxyl group required for DNA chain elongation, the growing chain of DNA is terminated. In addition, the incorporated acyclovir can trap viral DNA polymerase and prevent it from initiating other viral DNA replication. The viral polymerase has a greater affinity for acyclovir triphosphate than cellular DNA polymerase, resulting in little incorporation of acyclovir into cellular DNA. *In vitro*, acyclovir is most active against HSV-1 (average $EC_{50} = 0.04 \mu\text{g ml}^{-1}$), HSV-2 ($0.10 \mu\text{g ml}^{-1}$), and VZV ($0.50 \mu\text{g ml}^{-1}$). Varicella virus is much less susceptible to acyclovir than is HSV, and hence, higher doses of acyclovir are required in the treatment of VZV infections. EBV TK has poor efficiency to utilize acyclovir as substrate, therefore, higher acyclovir concentrations are required for EBV inhibition. CMV, which lacks a virus-specific TK, is relatively resistant.

The bioavailability of oral formulations of acyclovir is 15–30%. Peak concentrations of approximately 0.57 and $1.57 \mu\text{g ml}^{-1}$ are attained after multidose oral administration of 200 or 800 mg of acyclovir, respectively. Higher plasma acyclovir levels are achieved with intravenous administration. The plasma half-life is 2–3 h in older children and adults with normal renal function and 2.5–5 h in neonates with normal creatinine clearance. The elimination of acyclovir is prolonged in individuals with renal dysfunction, with a half-life of approximately 20 h in persons with end-stage renal disease. Acyclovir is minimally metabolized and approximately 85% is excreted unchanged in the urine via renal tubular secretion and glomerular filtration.

Clinical indications

For most of the clinical indications of acyclovir, valacyclovir and famciclovir are as effective, safe, and convenient alternatives. The clinical applications of valacyclovir and famciclovir are detailed in section 'Clinical indications' under 'Valacyclovir' and in section 'Clinical indications' under 'Penciclovir and Famciclovir,' respectively.

Genital herpes

Initial and recurrent episodes of genital HSV infection can be treated with acyclovir, and recurrent episodes can be suppressed with acyclovir. Topical acyclovir is not an effective treatment for genital HSV. Intravenous acyclovir ($15 \text{ mg kg}^{-1} \text{ day}^{-1}$ in three divided

doses for 5–7 days) is the most effective treatment for a first episode of genital herpes and results in a significant reduction in the median duration of viral shedding, pain, and time to complete healing (8 vs. 14 days) but is reserved for patients with systemic complications. Oral therapy (200 mg five times daily) is the standard treatment.

Recurrent genital herpes is less severe and resolves more rapidly than primary infection. Orally administered acyclovir (200 mg five times daily or 400 mg three times daily) for 7–10 days shortens the duration of signs and symptoms, virus shedding, and time to healing by 2, 7, and 4 days, respectively, when initiated within 24 h of onset of symptoms.

Oral acyclovir administration effectively suppresses recurrent genital herpes. Daily administration of acyclovir reduces the frequency of recurrences by up to 80%, and 25–30% of patients have no further recurrences while taking the drug.

Herpes labialis

Topical therapy for HSV-1 mouth or lip infections is of no clinical benefit. Orally administered acyclovir (200 or 400 mg five times daily for 5 days) reduces the time to loss of crust by approximately 1 day (7 vs. 8 days) but does not alter the duration of pain or time to complete healing.

Immunocompromised host

Immunocompromised individuals, such as those infected with HIV or transplant recipients, are afflicted with frequent and severe HSV infections. Clinical benefit from intravenous or oral acyclovir therapy is documented as evidenced by a significantly shorter duration of viral shedding and accelerated lesion healing. Oral acyclovir therapy in high doses in immunocompromised patients with herpes zoster is effective but valacyclovir is superior.

Herpes simplex encephalitis

HSV infection of the brain is the most common cause of sporadic fatal encephalitis in the United States. HSV-1 is predominantly the causative agent of herpes simplex encephalitis (HSE) (Whitley and Kimberlin, 2005). Acyclovir at a dose of 10 mg kg⁻¹ every 8 h (30 mg kg⁻¹ day⁻¹) for 10–14 days is the therapy of choice and reduces mortality from 70 to 19%. Furthermore, 38% of acyclovir recipients returned to normal neurologic function.

Neonatal HSV infection

HSV infection of the neonate is rare; with an estimated 1500 cases diagnosed annually in the United States from a birth cohort of more than 4 million (Kimberlin et al., 2013). HSV infection of the neonate is classified as: (1) skin, eye, or mouth (SEM) disease, (2) central nervous system (CNS) disease, and (3) disseminated (if there is evidence of visceral involvement) HSV disease. This classification system is predictive of severity and outcome of disease (Kimberlin et al., 2001; Whitley et al., 1991). The recommended treatment for neonatal herpes infection is 20 mg kg⁻¹ every 8 h of parenteral acyclovir with duration dictated by the extent of disease; 14 days for SEM disease, 21 days for CNS and disseminated disease. Oral acyclovir suppressive therapy for 6 months is recommended after parenteral acyclovir treatment (Kimberlin et al., 2013). For babies with SEM disease, 98% of acyclovir recipients developed normally 2 years after infection. For babies surviving encephalitis and disseminated disease, 43 and 57% of acyclovir recipients, respectively, developed normally.

Varicella

Varicella or chickenpox, is a common, highly contagious illness caused by VZV. It is primarily a disease of early childhood with 90% of cases occurring in children 1–14 years of age. Chickenpox is generally self-limiting in young children and is manifested by fever, mild constitutional symptoms, and an itchy, vesicular rash (Arvin, 2002). The disease is more severe in neonates, adults, and immunocompromised individuals. Oral acyclovir therapy when initiated within 24 h of the onset of the rash reduces the duration of fever, and the number of maximum lesions in immunocompetent children. At present, the clinical importance of acyclovir treatment in otherwise healthy children, in whom chicken pox is self-limiting and results in few complications, remains uncertain. Furthermore, the widely use of the varicella vaccine to protect against VZV will make the use of acyclovir for immunocompetent children with chickenpox obsolete.

Acyclovir therapy of chicken pox in immunocompromised host substantially reduces morbidity and mortality. Intravenous acyclovir treatment (500 mg m⁻² of body surface area or 10–12 mg kg⁻¹ every 8 h for 7–10 days) improved the outcome, as evidenced by a reduction of VZV pneumonitis from 45 to <5%. Oral acyclovir therapy is not indicated for immunocompromised host with chicken pox. The bioavailability of valacyclovir makes it an attractive alternative.

Herpes zoster

Herpes zoster or shingles is caused by the reactivation of VZV, which resides in a latent state in the sensory ganglia following primary varicella (chicken pox) infection (Dworkin et al., 2007). Acute herpes zoster is a painful, debilitating condition, especially in older adults. The risk of zoster-associated pain persisting after the healing of the rash correlates with increasing age. Intravenous acyclovir therapy of herpes zoster in the normal host produces some acceleration of the healing of the rash, and resolution of pain (both acute neuritis and zoster-associated pain). Oral acyclovir (800 mg five times a day) administration results in accelerated healing of the rash and reduction in the severity of acute neuritis. Oral acyclovir treatment of zoster ophthalmicus reduces the incidence of serious ocular complications such as keratitis and uveitis. Intravenous acyclovir therapy

significantly reduces the frequency of cutaneous dissemination and visceral complications of herpes zoster in immunocompromised adults. Acyclovir is the standard therapy at a dose of 10 mg kg^{-1} (body weight) or 500 mg m^{-2} (body surface area) every 8 h for 7–10 days.

Resistance

The most common mechanism for conferring acyclovir resistance is mutations in the HSV genome resulting in a deficiency or alteration in viral TK activity. Occasionally, HSV strains are TK altered and maintain the ability to phosphorylate the natural substrate, thymidine, but selectively lose the ability to phosphorylate acyclovir. Mutation of the viral DNA polymerase gene resulting in failure to incorporate the acyclovir triphosphate in progeny DNA molecules is an alternate, but infrequent, mechanism that may result in HSV resistance to acyclovir.

Resistance to acyclovir is uncommon, with prevalence of 0.1–0.4% and 5–6% in immunocompetent and immunocompromised patients, respectively (Englund et al., 1990; Morfin and Thouvenot, 2003). Acyclovir-resistant isolates of VZV have been identified much less frequently than acyclovir-resistant HSV but have been recovered from marrow transplant recipients and AIDS patients (Lyall et al., 1994). The acyclovir-resistant VZV isolates all had altered or absent viral TK function but remained susceptible to vidarabine and foscarnet, which do not require viral TK for their activity.

Adverse effect

Acyclovir therapy is associated with few adverse effects. The most common complaints associated with acyclovir therapy include nausea, diarrhea, and headache. Rapid infusions of intravenous acyclovir can result in reversible crystalline nephropathy. A few reports have linked intravenous acyclovir use with CNS disturbances, including agitation, hallucinations, disorientation, tremors, and myoclonus (Cohen et al., 1984; Wade and Meyers, 1983).

Data on outcomes from pregnant mothers exposed to acyclovir during pregnancy showed that the rate of birth defects did not exceed that expected in the general population and the pattern of defects did not differ from those in untreated women.

Valacyclovir

Valacyclovir

Chemistry, mechanism of action, and antiviral activity

Valacyclovir, is a prodrug of acyclovir (the L-valyl ester of acyclovir). Valacyclovir is rapidly metabolized into acyclovir and valine by the enzyme valacyclovir hydrolase (esterase) found in the brush border of the gastrointestinal tract, and the liver. Valacyclovir provides a high bioavailability of acyclovir, threefold to fivefold higher than that obtained with oral acyclovir, and is equivalent to plasma levels achieved with doses of intravenous acyclovir. The mechanism of action and antiviral activity spectrum of valacyclovir are similar to that as described for acyclovir.

Clinical indications

The antiviral spectrum of valacyclovir encompasses HSV-1, HSV-2, VZV, and CMV. It is effective for treatment of HSV-1 and HSV-2 infections in immunocompetent individuals; initial episode of genital herpes (1 g, twice daily for 10 days); episodic therapy for recurrent herpes labialis (2 g, twice a day for 1 day) and recurrent genital herpes (1 g or 500 mg, twice a day for 3–5 days); and suppression of recurrent genital herpes (1 g or 500 mg, once a day).

For immunocompromised patients, valacyclovir is effective for episodic therapy (1 g, twice a day for >5 days) and suppression of recurrent genital herpes (500 mg, twice a day, or 1 g, once a day). Valacyclovir (1 g, three times daily for 7–10 days) is superior to acyclovir for the reduction of pain associated with shingles.

Resistance

The mechanism of resistance to valacyclovir is similar to that of acyclovir.

Adverse effects

Valacyclovir has similar side effect profile as acyclovir; however, no crystalline nephropathy has been reported with its use.

Cidofovir

Chemistry, mechanism of action, and antiviral activity

Cidofovir, (S)-1-(3-hydroxy-2-phosphonylmethoxypropyl) cytosine (HPMPC), is an acyclic phosphonate nucleotide analogue of deoxycytidine monophosphate. Cidofovir has a single phosphate group attached therefore it does not require viral enzymes for conversion to the monophosphate, cellular kinases sequentially phosphorylate the monophosphate to its active triphosphate metabolite. The triphosphate metabolite then serves as a competitive inhibitor of DNA polymerase. The active form of the drug exhibits a 25- to 50-fold greater affinity for the viral DNA polymerase, compared with the cellular DNA polymerase, thereby selectively inhibiting viral replication. Owing to its unique phosphorylation requirements for activation, cidofovir usually maintains activity against acyclovir- and foscarnet-resistant HSV isolates, as well as ganciclovir- and foscarnet-resistant CMV mutants. Cidofovir is less potent than acyclovir *in vitro*; however, cidofovir persists in cells for prolonged periods, increasing drug activity. In addition, cidofovir produces active metabolites with long half-lives (17–48 h), permitting once weekly dosing. Cidofovir has *in vitro* activity against VZV, EBV, HHV-6, HHV-8, HPV, polyomaviruses, orthopoxviruses, and adenovirus. Unfortunately, cidofovir concentrates in kidney cells 100 times greater than in other tissues and produces severe proximal convoluted tubule nephrotoxicity when administered systemically. Cidofovir has limited and variable oral bioavailability (2–26%), therefore, it is administered intravenously.

Clinical indication

Cidofovir is licensed for treatment of CMV retinitis and has been used to treat acyclovir-resistant HSV infection. The dosing regimen is 5 mg kg⁻¹ per week during the first 2 weeks, then 5 mg kg⁻¹ every other week, with sufficient hydration and coadministration of oral probenecid to prevent nephrotoxicity. There are anecdotal reports that dividing the 5 mg kg⁻¹ weekly dose into three doses given alternate days in a week may reduce renal toxicity substantially.

Resistance

The development of resistance with clinical use is uncommon; however, mutations in CMV DNA polymerase can mediate altered susceptibility.

Adverse effects

Nephrotoxicity is the principal adverse event associated with systemic administration of cidofovir, occurs in 30–50% of recipients. Other reported side effects include neutropenia, fever, diarrhea, nausea, headache, rash, anterior uveitis, and ocular hypotonia.

Foscarnet

Chemistry, mechanism of action, and antiviral activity

Foscarnet, is an inorganic pyrophosphate analogue of phosphonoacetic acid that inhibits all HHVs, including most ganciclovir-resistant CMV isolate and acyclovir-resistant HSV and VZV strains. It inhibits DNA polymerase by blocking the pyrophosphate-binding site and preventing cleavage of pyrophosphate from deoxynucleotide triphosphates. Unlike acyclovir, which requires activation by a virus-specific TK, foscarnet acts directly on the virus DNA polymerase. Thus, TK-deficient, acyclovir-resistant herpesviruses remain sensitive to foscarnet.

The oral bioavailability of foscarnet is about 20%. The cerebrospinal fluid (CSF) concentration of foscarnet is approximately two-thirds of the plasma level. Renal excretion is the primary route of clearance of foscarnet with >80% of the dose appearing in the urine. Bone sequestration also occurs, resulting in complex plasma elimination.

Clinical indications

The principal indications are CMV retinitis in AIDS patients, and mucocutaneous acyclovir-resistant (viral TK-deficient) or penciclovir-resistant HSV and VZV infections in immunocompromised patients.

Mucocutaneous HSV infections and those caused by VZV in immunocompromised host can be treated with foscarnet at dosages lower than that for the management of CMV retinitis.

Resistance

Isolates of HSV, CMV, and VZV resistant to foscarnet develop both in the laboratory and in the clinical setting (Safrin et al., 1994; Wagstaff and Bryson, 1994). These isolates are all DNA polymerase mutants.

Adverse effects

Foscarnet toxicity includes mainly nephrotoxicity (acute tubular necrosis and interstitial nephritis), metabolic and hematologic abnormalities, and CNS side effects (Deray et al., 1989; MacGregor et al., 1991). Patients may develop isolated or combined hypomagnesemia, hypocalcemia, hypokalemia, and hypophosphatemia. CNS side effects include headache, seizures, irritability, tremor, and hallucination. Other reported side effects include fever, rash, painful genital ulcerations, diarrhea, nausea, and vomiting.

Ganciclovir and Valganciclovir

Chemistry, mechanism of action, and antiviral activity

Ganciclovir [9-(1,3-dihydroxy-2-propoxymethyl) guanine] is a nucleoside analogue that differs from acyclovir by having a hydroxymethyl group at the 3' position of the acyclic side chain. It has 8–20 times greater *in vitro* activity against CMV, and as active as acyclovir against HSV-1 and HSV-2 and almost as active against VZV. Like acyclovir, the first step of phosphorylation to ganciclovir monophosphate in herpesvirus-infected cells depends on virus-encoded enzymes. In cells infected by HSV-1 or HSV-2, TK catalyzes the phosphorylation of ganciclovir to ganciclovir monophosphate. Because CMV lacks the gene for TK, the enzyme that catalyzes the initial phosphorylation of ganciclovir in CMV-infected cells is the phosphotransferase encoded by *UL97* gene. The final phosphorylation steps to the di- and triphosphate is by cellular kinases. Ganciclovir triphosphate serves as a competitive inhibitor of herpes viral DNA polymerase and inhibits the incorporation of guanosine triphosphate into viral DNA. Incorporation of ganciclovir triphosphate into the growing viral chain results in slowing and subsequent cessation of DNA chain elongation. Intracellular ganciclovir triphosphate concentrations are at least tenfold higher in CMV-infected cells than uninfected cells.

The oral bioavailability of ganciclovir is poor (5–7%). Concentrations of ganciclovir in biologic fluids, including aqueous humor and CSF, are less than plasma levels. The plasma elimination half-life is 2–4 h for individuals with normal renal function.

The kidney is the major route of clearance of ganciclovir, and therefore, impaired renal function requires adjustment of dosage. The pharmacokinetics of ganciclovir in neonates is similar to that in adults.

Valganciclovir, L-valine ester of ganciclovir, serves as oral prodrug of ganciclovir. Valganciclovir is orally bioavailable (approximately 60%) and is rapidly converted to ganciclovir after absorption. Its mechanism of action and spectrum of activity are similar to that of ganciclovir. Oral valganciclovir can be given in doses that result in serum levels that approximate ganciclovir serum levels achieved with intravenous ganciclovir. Oral valganciclovir is convenient to use and may replace intravenous ganciclovir for initial and maintenance treatment.

Clinical indications

Ganciclovir is approved for treatment and chronic suppression of CMV retinitis in AIDS or other immunocompromised patients, and prophylaxis or preemptive treatment of CMV infection in high-risk transplant recipients. It is also effective for CMV syndromes, including CMV pneumonia, CMV colitis, and gastrointestinal infection in AIDS and transplant patients. In immunocompromised patients, therapy with ganciclovir requires an induction and maintenance phases. The induction dose is $10 \text{ mg kg}^{-1} \text{ day}^{-1}$ in two divided doses given for 14–21 days, and a maintenance dose of $5 \text{ mg kg}^{-1} \text{ day}^{-1}$ given once daily for 5–7 days per week. Oral valganciclovir dosage is 900 mg twice a day, and 900 mg once a day for induction and maintenance therapy, respectively (Balfour, 1999).

Ganciclovir is now recommended for treatment of neonates congenitally infected with CMV. In a phase III randomized controlled trial, ganciclovir therapy (6 mg kg^{-1} per dose administered twice a day for 6 weeks) protected infants from hearing deterioration beyond one year of life and reduced incidence of neurodevelopmental delays (Kimberlin et al., 2003; Oliver et al., 2009). Oral valganciclovir may become available for treatment of congenital CMV disease in the near future. In a randomized trial, valganciclovir treatment (16 mg kg^{-1} per dose every 12 h for six months) of newborns with congenital CMV disease was associated with improved head circumference and developmental milestones, and decreased risk of hearing loss or progression of hearing loss.

Resistance

In immunocompromised patients receiving prolonged therapy, the prevalence of resistance exceeds 8%. There are two mechanisms of resistance by CMV to ganciclovir: (1) The alteration of the CMV phosphonotransferase (coded by CMV *UL97* gene) (Markham and Faulds, 1994) reduces intracellular phosphorylation of ganciclovir, and (2) mutations in the CMV DNA polymerase (coded by CMV *UL54* gene). Resistance is associated with decreased sensitivity up to 20-fold. Occasionally, strains of HSV that are resistant to acyclovir because of TK deficiency are also much less sensitive to ganciclovir.

Adverse effects

The most important side effects of ganciclovir therapy are the development of neutropenia, and thrombocytopenia. Neutropenia occurs in approximately 24–38% of patients. The neutropenia is usually reversible with dosage adjustment of ganciclovir, or withholding of treatment. Thrombocytopenia occurs in 6–19% of patients.

Ganciclovir has gonadal toxicity in animal models, most notably as a potent inhibitor of spermatogenesis. It causes an increased incidence of tumors in the preputial gland of male mice, a finding of unknown significance. As an agent affecting DNA synthesis, ganciclovir has carcinogenic potential.

Penciclovir and Famciclovir

Penciclovir

Famciclovir

Chemistry, mechanism of action, and antiviral activity

Penciclovir [9-(4-hydroxy-3-hydroxymethylbut-1-yl)] a guanine nucleoside analogue is structurally similar to ganciclovir, differing only by the substitution of a methylene bridge for the ether oxygen in the acyclic ribose part of the molecule. Its metabolism and mechanism of action are similar to those of acyclovir, except that it is not an obligate DNA-chain terminator. The *in vitro* inhibitory effects of penciclovir on HSV-1, HSV-2, and VZV are similar to those of acyclovir. The oral bioavailability of penciclovir is poor (<5%). Famciclovir, a prodrug of penciclovir with improved bioavailability (approximately 77%), is the diacetyl ester of 6-deoxy penciclovir [9-(4-hydroxy-3-hydroxymethylbut-1-yl)-6-deoxyguanine]. It is well absorbed after oral administration and is rapidly metabolized to penciclovir by deacetylation in the gastrointestinal tract, and liver, after which it is oxidized by the liver at the position 6 of the purine ring. Penciclovir is phosphorylated more efficiently than acyclovir in HSV- and VZV-infected cells. Host cell kinases phosphorylate both penciclovir and acyclovir to a small but comparable extent. The preferential metabolism in HSV- and VZV-infected cells is the major determinant of its antiviral activity. Penciclovir triphosphate has, on average, a tenfold longer intracellular half-life than acyclovir triphosphate in HSV-1-, HSV-2-, and VZV-infected cells after drug removal. Because penciclovir is more stable, it has longer antiviral activity, allowing for less frequent dosing. Both compounds have good activity against HSV-1, HSV-2, and VZV. Penciclovir, like acyclovir, is relatively inactive against CMV and EBV. Penciclovir is active against hepatitis B.

Penciclovir is eliminated rapidly and almost unchanged by active tubular secretion and glomerular filtration by the kidneys. The elimination $T_{1/2}$ in healthy subjects is approximately 2 h.

Clinical indications

Famciclovir is available in an oral preparation for treatment of HSV-1, HSV-2, and VZV infections. It is used in the treatment of the following conditions: initial episodes of genital herpes (250 mg, three times a day for 10 days), episodic treatment of recurrent genital herpes (125 mg, twice a day for 5 days), suppression of recurrent genital herpes (250 mg, twice a day), and for shingles (500 mg, every 8 h for 7 days). For immunocompromised patients, famciclovir is efficacious for episodic treatment of recurrent genital herpes (500 mg, twice a day for 7 days). Compared with acyclovir, famciclovir is as effective, safe, and well tolerated in the treatment of HSV infections in HIV-infected individuals. Famciclovir is also at least as effective as acyclovir for ophthalmic zoster and for shingles and acute zoster pain in immunocompromised patients. Compared with valacyclovir, famciclovir is as effective, safe, and convenient in the treatment of zoster.

Penciclovir is available as a 1% cream for topical therapy of mucocutaneous HSV infections, particularly recurrent herpes labialis (cold sores). Topical penciclovir 1% is approved for episodic therapy of herpes labialis and applied every 2 h during waking hours for 4 days. It accelerates lesion healing and resolution of pain by about 1 day. It is available over-the-counter in many countries.

Resistance

HSV and VZV isolates resistant to penciclovir have been identified in the laboratory. In clinical trials, penciclovir-resistant HSV was isolated from 0.22% immunocompetent patients and 2.1% of immunocompromised patients (Sarisky et al., 2003). Resistance is attributed to alterations or deficiencies of TK and DNA polymerase.

Adverse effects

Therapy with oral famciclovir is well tolerated, being associated only with headache, diarrhea, and nausea. Preclinical studies of famciclovir indicated that chronic administration was tumorigenic (murine mammary tumors) and causes testicular toxicity in other rodents.

Idoxuridine and Trifluorothymidine

Chemistry, mechanism of action, and antiviral activity

Idoxuridine (5-iodo-2'-deoxyuridine), and trifluorothymidine (5-trifluoromethyl-2'-deoxyuridine) are thymidine analogues. When administered systemically, these nucleosides are phosphorylated by both viral and cellular kinases to active triphosphate derivatives, which inhibit both viral and cellular DNA synthesis. Parenteral administration results in potent antiviral activity but also sufficient host cytotoxicity to prevent the systemic use of these drugs. The toxicity of these compounds is not significant when applied topically to the eye in the treatment of HSV keratitis. Both idoxuridine and trifluorothymidine are effective and licensed for treatment of HSV keratitis. Topically applied idoxuridine or trifluorothymidine will penetrate cells of the cornea. Low levels of drugs can be detected in the aqueous humor.

Clinical indications

Trifluorothymidine is the most efficacious of these compounds, and the treatment of choice for HSV keratitis (1 drop of 1% ophthalmic solution instilled in each eye, up to nine times a day). Idoxuridine was the first antiviral compound to receive FDA approval in 1963 for treatment of HSV keratitis.

Resistance

Trifluorothymidine-resistant HSV strains with altered TK substrate specificity have been selected for *in vitro*. However, clinical significant resistance has not been established.

Adverse effects

The ophthalmic preparation of idoxuridine and trifluorothymidine causes local discomfort, irritation, photophobia, edema of the eyelids, and less commonly, hypersensitivity reactions as well as superficial punctate or epithelial keratopathy.

Vidarabine

Chemistry, mechanism of action, and antiviral activity

Vidarabine (vira-A, adenine arabinoside, and 9-D-arabinofuranosyl adenine) is active against HSV, VZV, and CMV. Vidarabine is a purine nucleoside analogue that is phosphorylated intracellularly to its mono-, di-, and triphosphate derivatives. Thus, unlike acyclovir, conversion of vidarabine to its active intracellular derivative does not require viral enzymes at any of the phosphorylation

steps. The triphosphate derivative competitively inhibits DNA dependent DNA polymerases of some DNA viruses approximately 40 times more than those of host cells. In addition, vira-A is incorporated into terminal positions of both cellular and viral DNA, thus inhibiting elongation. Viral DNA synthesis is blocked at lower doses of drug than is host cell DNA synthesis, resulting in a relatively selective antiviral effect. However, large doses of vira-A are cytotoxic to dividing host cells.

The use of vidarabine was replaced by acyclovir because of poor solubility and toxicity. It is no longer available as an intravenous formulation. However, vidarabine should be recognized historically as the first antiviral agent licensed in 1977 for systemic treatment.

Clinical indications

Although trifluorothymidine is the antiviral agent of choice for the topical treatment of HSV keratitis, in patients in whom trifluorothymidine cannot be used vidarabine is a suitable alternative. Topical vidarabine is superior to idoxuridine in the treatment of HSV ocular infections.

Resistance

Resistance to vidarabine is conferred by mutations in the viral DNA polymerase gene. The degree of maximal resistance to vidarabine is fourfold, much lower than the 100-fold resistance to acyclovir with similar DNA polymerase resistant mutations. Acyclovir-resistant clinical HSV isolates are always susceptible *in vitro* to vidarabine.

Adverse effects

Ocular toxicity consists of occasional hyperemia and increased tearing, both of low incidence.

Fomivirsen

Chemistry, mechanism of action, and antiviral activity

Fomivirsen is a 21-nucleotide phosphorothioate oligonucleotide that inhibits CMV replication through an antisense mechanism. Its oligonucleotide sequence (5'-GCG TTT GCT CTT CTT CTT GCG-3') is complementary to a sequence in mRNA transcripts of the major immediate early region 2 (IE2) of CMV, which encodes for several proteins responsible for the viral gene expression that are essential for the production of infectious viral particles. Binding of fomivirsen to the target mRNA results in inhibition of IE2 protein synthesis, with subsequent inhibition of viral replication. *In vitro*, fomivirsen inhibits CMV replication in a dose-dependent manner, with a mean IC_{50} of between 0.03 and 0.2 $\mu\text{mol l}^{-1}$. Pharmacokinetic assessment of fomivirsen in humans after intraocular administration is limited. In a rabbit model, intraocular administration revealed first-order kinetics with half-life of 62 h. Fomivirsen is cleared from the vitreous in rabbits during the course of 7–10 days by a combination of tissue distribution and metabolism. No systemic absorption has been observed after intravitreal administration in humans.

Clinical indications

Fomivirsen is indicated for use in HIV patients with CMV retinitis who are intolerant of or have contraindication to other treatment for CMV retinitis or in whom the disease is recalcitrant to ganciclovir or cidofovir treatment. It has activity against cidofovir- and ganciclovir-resistant strains of CMV.

Resistance

CMV strains with tenfold decreased susceptibility have been selected *in vitro*. However, no resistant clinical isolates have been reported.

Adverse effects

Adverse events of fomivirsen are uveitis, including iritis and vitritis, occurring in approximately 25% of patients. These reactions are usually transient or reversible with topical corticosteroids treatment.

New Prospects for Therapy of Herpesvirus Infections

All the licensed antiviral agents for herpes infections ultimately target the viral HSV DNA polymerase, which is essential for virus replication. Recent drug discovery efforts have not only focused on improving the efficacy and safety profile of current antivirals but also explored new viral targets (Kleymann et al., 2002). A prodrug of cidofovir (CMX001) has demonstrated that the prodrug approach can not only improve oral absorption but also reduce the toxicity of the parent compound. Pritelivir (AIC316), a helicase–primase inhibitor, with preclinical pharmacological profile that outperforms the current standard HSV treatment has

shown promise in a Phase II trial (Vere Hodge and Field, 2013; Wald et al., 2014; Weller and Kuchta, 2013). Recent discovery of antiviral activity of letermovir (AIC246), a terminase inhibitor, is a proof of concept that herpes virus terminase enzyme is a viable target for new HSV therapies (Goldner et al., 2011). The ultimate breakthrough for the treatment of herpes virus infection will be the discovery of agents or innovative strategies to eliminate herpes latency.

Therapeutics for Respiratory Virus Infections

Amantadine and Rimantadine

Chemistry, mechanism of action, and antiviral activity

Amantadine (1-adamantanamine hydrochloride) and rimantadine (α -methyl-1-adamantanemethylamine hydrochloride) are symmetric tricyclic amines with narrow spectrum of activity, being useful only against influenza A infections. Rimantadine is fourfold to tenfold more active than amantadine. The mechanism of action of these drugs relates to the influenza A virus M2 protein, an integral transmembrane protein that functions as an ion channel for this virus and is activated by pH. The drop in pH accompanying the hydrogen flux facilitates the dissociation of the M2 protein from the ribonucleoprotein complexes so that the ribonucleoprotein can enter the cell nucleus and initiate replication. By interfering with the function of the M2 protein, amantadine and rimantadine inhibit the acid-mediated dissociation of the matrix protein from the ribonuclear protein complex within endosomes. This event occurs early in the viral replication cycle. The consequences of these drugs are the potentiation of acidic pH-induced conformational changes in the viral hemagglutinin during its intracellular transport.

Absorption of rimantadine is slower compared with that of amantadine. Amantadine is excreted unchanged in the urine by glomerular filtration and, likely, tubular secretion. The plasma elimination $T_{1/2}$ is approximately 12–18 h in individuals with normal renal function. However, the elimination $T_{1/2}$ increases in the elderly with impaired creatinine clearance. Rimantadine is extensively metabolized following oral administration, with an elimination $T_{1/2}$ of 24–36 h. Approximately 15% of the dose is excreted unchanged in the urine.

Clinical indications

Amantadine and rimantadine are licensed for the chemoprophylaxis and treatment of influenza A infections. Prophylaxis with either drug prevents approximately 50–60% of infections and 70–90% of clinical illnesses caused by type A influenza virus. Because of a lower incidence of side effects associated with rimantadine, it is used preferentially. Rimantadine can be given to any unimmunized member of the general population who wishes to avoid influenza A, but prophylaxis is especially recommended for control of presumed influenza outbreaks in institutions housing high-risk persons. High-risk individuals include adults and children with chronic disorders of the cardiovascular or pulmonary systems. Prophylaxis also is indicated if the vaccine may be ineffective because the epidemic strain differs substantially from the vaccine strain of influenza A, and for the 2 weeks after vaccination if influenza A already is active in the community.

Amantadine and rimantadine also have been shown to be effective in treatment of influenza A infections in adults and children if treatment is initiated within 48 h of the onset of symptoms (Couch, 2000). Drug therapy results in reduction in the duration of viral excretion, fever, and other systemic complaints, as well as earlier resumption of normal activities, in comparison with placebo. On average, the duration of illness is shortened by about 1 day. Amantadine and rimantadine are given orally at 200, and 300 mg day⁻¹, respectively.

Resistance

Resistance to amantadine and rimantadine results from point mutations in the RNA sequence encoding the M2 protein transmembrane domain. Resistance typically appears in the treated subjects within 2–3 days of initiating therapy. About 25–35% of treated patients shed resistant strains by the 5th day of treatment (2006). The clinical significance of isolating resistant strains from the treated subject is not clear; infection and illness in immunocompetent people infected with a drug-resistant virus are similar to those in patients infected with drug-sensitive virus.

Adverse effects

Although the spectrum of adverse events associated with amantadine and rimantadine are qualitatively similar, they are less frequent and less severe with rimantadine. Amantadine is reported to cause side effects in 5–10% of healthy young adults taking the standard adult dose of 200 mg day⁻¹. These side effects are usually mild and cease soon after amantadine is discontinued, although they often disappear with continued use of the drug. CNS side effects, which occur in 5–33% of patients, are most common and include difficulty in thinking, confusion, lightheadedness, hallucinations, anxiety, and insomnia. More severe adverse effects (e.g., mental depression and psychosis) are usually associated with doses exceeding 200 mg daily. About 5% of patients complain of nausea, vomiting, or anorexia. CNS adverse effects associated with rimantadine administration are significantly less; however, rimantadine has been associated with exacerbations of underlying seizure disorders.

Zanamivir and Oseltamivir

Chemistry, mechanism of action, and antiviral activity

Zanamivir (4-guanidino-2,3-dideoxy-2,3-didehydro-*N*-acetylneuraminic acid), and oseltamivir [ethyl ester of (3*R*,4*R*,5*S*)-4-scytamido-5-amino-3-(1-ethylpropoxyl)-1-cyclohexane-1-carboxylic acid] are sialic acid analogue that competitively inhibit influenza virus neuraminidase (NA). Influenza virus NA is located on the surface of the virus and is responsible for cleaving terminal sialic acid residues, which are essential for the release of the virus from infected cells, viral aggregation, and spread within the respiratory tract. Influenza NA also decreases viral inactivation by respiratory mucous. The lipophilic side chain of zanamivir and oseltamivir binds to the influenza virus NA, blocking its ability to cleave sialic acid residues. Zanamivir and oseltamivir are effective against both influenza A and influenza B.

Zanamivir has poor oral bioavailability and therefore it is administered by oral inhalation. More than 75% of an orally inhaled dose of zanamivir is deposited in the oropharynx, approximately 13% of this is distributed to the airways and lungs. Local respiratory mucosal concentrations of zanamivir exceeds 1000 ng ml⁻¹ in sputum for 6 h after inhalation (i.e., over and above the concentration required to inhibit influenza A and B viruses). Approximately 10% of inhaled dose is absorbed systemically; peak serum concentrations range from 17 to 142 ng ml⁻¹ within 2 h of administration of a 10 mg dose. The plasma *T*_{1/2} is between

2.5 and 5 h. Systemically absorbed zanamivir is excreted unchanged in the urine. Although serum concentrations of zanamivir increase with decreasing creatinine clearance, no adjustment in dosing is necessary for renal insufficiency because of the limited amount of systemically absorbed drug.

Oseltamivir is an ethyl ester prodrug that, following hydrolysis by hepatic esterases, is converted to the active compound, oseltamivir carboxylate. Approximately 75% of orally administered oseltamivir reaches the systemic circulation in the form of oseltamivir carboxylate. Oseltamivir carboxylate is eliminated unchanged by renal excretion through glomerular filtration and tubular secretion. The elimination $T_{1/2}$ of oseltamivir carboxylate is 6–10 h. Serum concentrations of the drug increase in the presence of declining renal function, and dose adjustment is recommended in patients with renal insufficiency.

Clinical indications

Zanamivir and oseltamivir are used for treatment and prevention of influenza A and B infections. Treatment of otherwise healthy adults and children with zanamivir and oseltamivir reduces the duration of symptoms by 0.4 and 1 days, and provides 29–43% relative reduction in the odds of complications when given within 48 h of onset of symptoms. These drugs also significantly diminish viral replication in respiratory secretions. Zanamivir is available as dry powder for inhalation using a breath-activated Diskhaler delivery system. The recommended dose of zanamivir in patients >7 years is 10 mg twice daily for 5 days, while oseltamivir is given at 75 mg twice a day for 5 days.

Inhaled zanamivir, 10 mg once daily given for 4 weeks as seasonal prophylaxis, reduces the likelihood of laboratory confirmed influenza (with or without symptoms) by 34%, influenza disease by 67%, and influenza disease with fever by 84%. Oseltamivir administered for 6 weeks during the peak of influenza season significantly reduces the risk of contracting influenza. The protective efficacy of oseltamivir in preventing culture-proven influenza is about 90%.

Resistance

Viruses resistant to zanamivir and oseltamivir have been generated after *in vitro* passage in cell culture. Clinical influenza virus isolates with reduced susceptibility to both NA inhibitors have been reported (de Jong et al., 2005). There are two mechanisms of resistance: mutations in the hemagglutinin receptor-binding site, and mutations in the conserved portions of the NA enzyme active site. In general, resistant viruses with mutations in the NA enzyme are thought to have decreased infectivity and fitness and therefore less likely to be transmitted.

Adverse effects

Both NA inhibitors are generally well tolerated. Adverse events following administration of oseltamivir have primarily been gastrointestinal with nausea and vomiting occurring in some patients. Inhalation of zanamivir has resulted in bronchospasm and reduced forced expiratory volume (FEV1). Zanamivir should be used with caution in individuals with reactive airway diseases or chronic obstructive pulmonary diseases.

Ribavirin

Chemistry, mechanism of action, and antiviral activity

Ribavirin (α -methyl-1-adamantane methylamine hydrochloride) has antiviral activity against a variety of RNA and DNA viruses. Ribavirin is a nucleoside analogue with poorly understood mechanism of action and probably virus-specific mechanism of action. However, its ability to alter nucleotide pools and the packaging of mRNA appears important. This process is not virus specific, but quite selective, in that infected cells produce more mRNA than noninfected cells. A major action is the inhibition by ribavirin-5'-monophosphate of inosine monophosphate dehydrogenase, an enzyme essential for DNA synthesis. This inhibition may have direct effects on the intracellular level of GMP and other nucleotide levels may be altered. The 5'-triphosphate of ribavirin inhibits the formation of the 5'-guanylation capping on the mRNA of vaccinia and Venezuelan equine encephalitis viruses. In addition, the triphosphate is a potent inhibitor of viral mRNA (guanine-7) methyltransferase of vaccinia virus.

The capacity of viral mRNA to support protein synthesis is markedly reduced by ribavirin. Ribavirin may inhibit influenza A RNA-dependent RNA polymerase.

Ribavirin can be administered orally (bioavailability of approximately 40–45%) or intravenously. Aerosol administration has become standard for the treatment of RSV infections in children. Oral doses of 600 and 1200 mg result in peak plasma concentrations of 1.3 and 2.5 $\mu\text{g ml}^{-1}$, respectively. Intravenous dosages of 500 and 1000 mg result in 17 and 24 $\mu\text{g ml}^{-1}$ plasma concentrations, respectively. Aerosol administration of ribavirin results in plasma levels that are a function of the duration of exposure. Although respiratory secretions will contain milligram quantities of drug, only microgram quantities (0.5–3.5 $\mu\text{g ml}^{-1}$) can be detected in the plasma.

The kidney is the major route of clearance of drug, accounting for approximately 40%. Hepatic metabolism also contributes to the clearance of ribavirin. Notably, ribavirin triphosphate concentrates in erythrocytes and persists for a month or longer. Likely, the persistence of ribavirin in erythrocytes contributes to its hematopoietic toxicity.

Clinical indications

Respiratory syncytial virus

Ribavirin is licensed for the treatment of carefully selected, hospitalized infants and young children with severe lower respiratory tract infections caused by RSV. Use of aerosolized ribavirin in adults and children with RSV infections reduced the severity of illness and virus shedding. However, placebo controlled trials have failed to demonstrate a consistent decrease in need for mechanical ventilation, duration of stay in intensive care unit, or duration of hospitalization among ribavirin recipients. The use of ribavirin for the treatment of RSV infections is controversial and remains discretionary. The most common adverse events following aerosol administration of ribavirin include bronchospasm and malfunction of ventilator delivery systems. The usual dosage of aerosolized ribavirin is 20 mg ml^{-1} of drug instilled in a small-particle aerosol generator (SPAG) and administered for 12–22 h day^{-1} for 3–6 days. To avoid potential exposure of health care workers to ribavirin, special containment delivery system in an isolation room with negative pressure is used.

Hepatitis C

Oral ribavirin in combination with interferon- α (IFN- α) and a direct-acting antiviral agent (DAA) is recommended for hepatitis C infection.

Lassa fever and hemorrhagic fever

Systemic ribavirin has demonstrated efficacy in the management of life-threatening infections caused by Lassa fever and hemorrhagic fever with renal syndrome. Oral ribavirin is recommended for prophylaxis against Lassa fever in exposed contacts.

Resistance

Treatment failures with ribavirin occur in some patients; however, resistance to ribavirin has not been identified as a clinical problem.

Adverse effects

Adverse effects attributable to aerosol therapy with ribavirin of infants with RSV include bronchospasm, pneumothorax in ventilated patients, apnea, cardiac arrest, hypotension, and concomitant digitalis toxicity. Pulmonary function test changes after ribavirin therapy in adults with chronic obstructive pulmonary disease have been noted. Reticulocytosis, rash, and conjunctivitis have been associated with the use of ribavirin aerosol. When given orally or intravenously, transient elevations of serum bilirubin and the occurrence of mild anemia have been reported. Ribavirin has been found to be teratogenic and mutagenic in preclinical testing. Its use is contraindicated in women who are or may become pregnant during exposure to the drug. Concern has been expressed about the risk to persons in the room of infants being treated with ribavirin aerosol, particularly females of childbearing age. Although this risk seems to be minimal with limited exposure, awareness and caution are warranted and, therefore, the establishment of stringent precautions for administration of ribavirin.

New Prospects for Therapy of Respiratory Viruses

While influenza pandemics have long posed a threat to humankind, a threat realized to varying extents in 1918, 1957, and 1968, particular concern has mounted of late due to continued sporadic human cases of H5N1 avian influenza in Southeast Asia, Eastern Europe, and Africa. Amantadine and rimantadine are not recommended for seasonal or avian influenza because circulating influenza A viruses as well as the H5N1 strains affecting humans in Southeast Asia are resistant to these medications. Zanamivir and oseltamivir are the only available options. To expand the antiviral drug arsenal against influenza, researchers have been testing a number of investigational agents, including peramivir and T-705. Although peramivir is a NA inhibitor administered intramuscularly. Preclinical studies in mice and ferrets revealed that the drug could protect 80% or more of animals exposed to pathogenic H5N1 influenza virus compared with 36% of untreated animals. A pyrazine derivative, T-705 (6-fluoro-3-hydroxy-2-pyrazinecarboxamide), is a viral RNA polymerase inhibitor in the preclinical testing stage.

The outbreaks of novel coronavirus infections such as severe acute respiratory syndrome (SARS) coronavirus (SARS-CoV)(Drosten et al., 2003) and Middle East respiratory syndrome coronavirus (MERS-CoV)(Guery et al., 2013), underscore the need for novel antiviral drugs for the control of future outbreaks of coronavirus and other respiratory viruses infections.

Therapeutics for Hepatitis

Interferons

Chemistry, mechanism of action, and antiviral activity

IFNs are glycoprotein cytokines (intercellular messengers) with a complex array of immunomodulating, antineoplastic, and antiviral properties. IFNs are currently classified as α , β , or γ , the natural sources of which, in general, are leukocytes, fibroblasts, and lymphocytes, respectively. Each type of IFN can be produced through recombinant DNA technology. The binding of IFN to the intact cell membrane is the first step in establishing an antiviral effect. IFN binds to the cellular receptors and activates secondary messengers to initiate production of multiple proteins, which are pivotal for the defense of the cell against viruses. The mechanism of action is rather complex (Thomas et al., 2003). The antiviral effects of IFN include degradation of viral mRNA, inhibition of viral protein synthesis, and prevention of the viral infection of cells. The immunomodulating effects of IFN include enhancement of antigen presentation by HLA I and II to the immune system, activation of natural killer (NK) cells and other immune cells, and increased cytokine production. IFNs are active against a wide spectrum of viruses with RNA viruses being more sensitive than DNA viruses.

IFNs are not orally bioavailable and are administered intramuscularly or subcutaneously (including into a lesion). There appears to be some variability in absorption between each of the three classes of IFN and, importantly, resultant plasma levels. Absorption of IFN- α is more than 80% complete after intramuscular or subcutaneous injection. Plasma levels are dose dependent, peaking 4–8 h after administration and returning to baseline between 18 and 36 h. However, the antiviral activity peaks at 24 h and then slowly decreases to baseline over about 6 days. IFN is eliminated by inactivation in various body fluids and metabolism in a number of organs. Negligible amounts are excreted in the urine unchanged.

IFN- α molecule covalently bonded to polyethylene glycol (PEG) improves the pharmacokinetic profile of IFN markedly. The pegylated forms of IFN- α (Peg-IFN- α) offer a more convenient once weekly instead of daily administration, are licensed for the treatment of hepatitis B and C.

Clinical indications

Hepatitis B

The major goals of therapy for hepatitis B are to prevent progression of the disease to cirrhosis, end stage liver disease or hepatocellular carcinoma (Chiaromonte et al., 1999; Yang et al., 2002). Three generally accepted indications for treatment are: (1) positive test for HBV DNA, (2) positive hepatitis B e antigen (HBeAg), and (3) alanine aminotransferase (ALT) level greater than two times normal. Treatment end points differ in HBeAg positive, and HBeAg negative disease. However, suppression of HBV replication to levels less than 1×10^4 copies per ml (2000 IU ml^{-1}) is regarded as a surrogate of treatment success with a resultant improvement in serum ALT and hepatic necroinflammatory disease.

Hepatitis B DNA polymerase level, a marker of replication, is reduced with standard IFN therapy. Clearance of serum HBeAg and HBV DNA polymerase occurs with treatment (30–40%). The use of pegylated forms of IFN has become common with the convenience of weekly dosing. Genotype and other baseline factors affect the response to PEG-IFN- $\alpha 2a$ in HBeAg-positive chronic hepatitis B. Patients with genotypes A and B have a better response in comparison with genotypes C and D patients.

Hepatitis C

The aim of therapy for chronic HCV infection is to decrease and ultimately prevent progressive liver damage leading to cirrhosis, liver failure, or hepatocellular carcinoma. Therapy for chronic HCV infection is indicated in patients with detectable HCV RNA viral load and persistently elevated ALT. Findings of cirrhosis, fibrosis, or even moderate inflammation on liver biopsy support the choice of therapeutic intervention; however, biopsy is not mandatory prior to treatment initiation. Standard IFN, either as monotherapy or in combination with ribavirin, has been used extensively for HCV infections. Combination therapy for 40 weeks resulted in sustained responses in more than 60% of patients. The standard treatment of HCV infection is either PEG-IFN- $\alpha 2a$ or PEG-IFN- $\alpha 2b$ given alone or in combination with ribavirin and a direct-acting antiviral agent (DAA). Genotypes 1 and 4 infections are associated with lower sustained virologic response than other HCV genotypes.

Resistance

Resistance to administered IFN has not been documented although neutralizing antibodies to recombinant IFNs have been reported. The clinical importance of this latter observation is unknown.

Adverse effects

Side effects are frequent with IFN (both standard and pegylated) administration and are usually dose limiting. Influenza-like symptoms (i.e., fever, chills, headache, and malaise) commonly occur, but these symptoms usually become less severe with repeated treatments. Leukopenia is the most common hematologic abnormality, occurring in up to 26% of treated patients. Leukopenia is usually modest, not clinically relevant, and reversible upon discontinuation of therapy. Increased ALT levels may also occur as well as nausea, vomiting, and diarrhea. At higher doses of IFN, neurotoxicity is encountered, as manifested by personality changes, confusion, attention deficits, disorientation, and paranoid ideation.

Lamivudine

Chemistry, mechanism of action, and antiviral activity

Lamivudine is the (–) enantiomer of a cytidine analogue with sulfur substituted for the 3' carbon atom in the furanose ring [(–) 2',3'-dideoxy, 3'-thiacytidine]. It has significant activity *in vitro* against both HIV-1 and HIV-2 as well as HBV. Lamivudine is phosphorylated to the triphosphate metabolite by cellular kinases. The triphosphate derivative is a competitive inhibitor of the viral reverse transcriptase (Chang et al., 1992).

The oral bioavailability in adults is >80% for doses between 0.25 and 8.0 mg kg^{–1}. Peak serum concentrations of 1.5 µg ml^{–1} are achieved in 1–1.5 h and the plasma *T*_{1/2} is approximately 2–4 h. Lamivudine is eliminated by the kidneys unchanged by both glomerular filtration and tubular excretion, and dosages should be adapted to creatinine clearance.

Clinical indications

Lamivudine is effective as monotherapy for the treatment of chronic HBV infection (Dienstag et al., 1999) and in combination with other antiretroviral drugs for treatment of HIV infection. It is the first line drug for the treatment of HBeAg and anti-HBe positive disease. Elevated serum ALT levels have been shown to predict a higher likelihood of HBeAg loss in patients with chronic hepatitis B treated with lamivudine. Lamivudine is administered orally at 100 mg day^{–1} in the treatment of HBV infections, though the ideal dose could be higher.

Resistance

Resistance to lamivudine monotherapy develops within 6 months of therapy. The incidence of lamivudine resistance is 15–20% per year, with 70% patients becoming resistant after 5 years of treatment (Lok et al., 2003; Pawlotsky, 2003). It will be curious to know if lamivudine at higher doses will affect the incidence of resistance. Lamivudine resistance to HBV is conferred through HBV strains with mutations in the viral polymerase, within the catalytic domain (C domain), which includes the YMDD motif (e.g., M204V or M204I), and within the B domain (e.g., L180M or V173L) (Das et al., 2001). These mutants have a reduced replication capacity compared with the wild type HBV virus. Lamivudine resistance is managed by sequential treatment with either adefovir or entecavir. However, the advantage of sequential treatment compared to *de novo* combination therapy is questionable.

Adverse effects

Lamivudine has an extremely favorable toxicity profile. This may be partly because lamivudine does not affect mitochondrial DNA synthesis and its poor inhibition of human DNA polymerases (Chang et al., 1992). At the highest doses of 20 mg kg^{–1} day^{–1}, neutropenia is encountered but at a low frequency.

Adefovir Dipivoxil

Chemistry, mechanism of action, and antiviral activity

Adefovir dipivoxil, bis(pivaloyloxymethyl)ester of 9-(2-phosphonylmethoxyethyl) adenine, is an orally bioavailable prodrug of adefovir, a phosphonate acyclic nucleotide analogue of adenosine monophosphate. Adefovir is monophosphorylated and is not

dependent on initial phosphorylation by viral nucleoside kinases to exert its antiviral effect. The phosphorylation to the di- and triphosphate metabolites is by cellular kinases (Merta et al., 1992). The triphosphate competes with endogenous deoxyadenosine triphosphate (dATP) in incorporation to the nascent viral DNA resulting in premature termination of viral DNA synthesis due to the lack of a 3' hydroxyl group (De Clercq, 2004). It has activity against HIV, hepadnaviruses and herpesviruses. The bioavailability of adefovir dipivoxil in humans is about 40%. It has a long intracellular half-life of 18 h allowing for a once-daily dose. Clearance of adefovir is by renal excretion. Its pharmacokinetics is substantially altered in subjects with moderate and severe renal impairment.

Clinical indications

The efficacy of adefovir has been assessed in patients with HBeAg positive and negative disease and other settings in the spectrum of chronic hepatitis B infection. At the recommended dose of 10 mg once a day, adefovir resulted in significant improvement when compared with placebo (Marcellin et al., 2003): improvement in liver histology (53% vs. 25%), reduction in HBV DNA (3.52 vs. 0.55 log copies ml⁻¹), normalization of ALT (48% vs. 16%), and HBeAg seroconversion (12% vs. 6%). It is also useful for the treatment of lamivudine-resistant HBV infection (Schiff et al., 2007; Zoulim et al., 2009).

Resistance

Adefovir resistance occurs in approximately 6% of patients 3 years after adefovir monotherapy (Hadziyannis et al., 2005). Mutations in the HBV polymerase B domain (A181V/T) and the D domain (N236T) confer resistance to adefovir (Lacombe et al., 2006; Osioy et al., 2006).

Adverse effects

Nephrotoxicity is the major side effect of higher doses of adefovir (Hadziyannis et al., 2006; Schiff et al., 2007). It causes a proximal convoluted tubule lesion characterized by a rise in urea and creatinine. Other dose-related clinical adverse events have been gastrointestinal events, including nausea, anorexia and diarrhea. These are usually mild, intermittent and self-limited without the need for concomitant medications or dose interruption.

Entecavir

Chemistry, mechanism of action, and antiviral activity

Entecavir (2-amino-1,9-dihydro-9-[(1S,3R,4S)-4-hydroxy-3-(hydroxymethyl)-2-methylenecyclopentyl]-6H-purin-6-one), monhydrate is a guanosine nucleoside analogue. Entecavir is efficiently phosphorylated by cellular kinases to the active triphosphate metabolite. It affects three-steps in the replication of HBV: (1) prevent the priming of the HBV reverse transcriptase, (2) prevent reverse transcribing of the HBV pregenomic mRNA, and (3) inhibits DNA-dependent DNA synthesis (i.e., terminating viral DNA synthesis) (Seifer et al., 1998; Zoulim, 2006). The HBV polymerase binds preferentially to entecavir triphosphate, and entecavir triphosphate does not affect human mitochondrial DNA synthesis. The effect of entecavir on human cellular polymerase is minimal. Studies prior to approval of entecavir for HBV treatment suggested that entecavir did not have anti-HIV activity at clinical relevant concentrations. However, recent studies have suggested an anti-HIV activity of entecavir at drug concentrations in the low nanomolar range (McMahon et al., 2007; Sasadeusz, 2007).

Entecavir is well absorbed after oral administration achieving peak plasma concentrations between 0.6 and 1.5 h. Entecavir is not a substrate of the cytochrome P450 (CYP) enzyme system. It is eliminated primarily in the urine through glomerular filtration and

tubular secretion. The mean elimination $T_{1/2}$ of entecavir varies from 77 to 149 h in patients with normal function. The intracellular half-life of the triphosphate metabolite *in vitro* studies is about 15 h (Yamanaka et al., 1999).

Clinical indications

Entecavir was approved in March 2005, for the management of adult patients with chronic HBV infection who have active viral replication and/or elevation in liver transaminases or signs of active disease on histological examination. In phase III trials, responses achieved with entecavir surpassed previously published response rates for IFN- α -2b, lamivudine, and adefovir dipivoxil. With recent reports of an anti-HIV activity of entecavir, entecavir monotherapy probably should not be used in individuals with HIV-HBV coinfection who need HBV but not HIV treatment.

Resistance

The prevalence rate of resistance to entecavir in HBV-treatment naive is about 1.2%. However, virologic rebound and resistance have been reported in 43% of lamivudine-resistant patients after 4 year of switching treatment to entecavir. Entecavir resistance requires the following amino acid sequence changes in the reverse transcriptase domain of HBV; M204V/I+L184G, S202I, or M250V (Baldick et al., 2008).

Adverse effects

Most adverse events in the phase III studies were mild and comprised of headache, upper respiratory tract infections, cough, fatigue, pharyngitis, abdominal pain, and gastrointestinal upset. The most common laboratory abnormality was ALT level greater than five times the upper limit of normal. Monitoring for long-term toxicity is needed.

Telbivudine

Chemistry, mechanism of action, and antiviral activity

Telbivudine (β -L-2'-deoxythymidine) is an L-configured nucleoside with potent and specific activities against HBV and other hepadnaviruses. Telbivudine is a competitive inhibitor of both HBV viral reverse transcriptase and DNA polymerase. Telbivudine is phosphorylated by cellular kinases to the triphosphate metabolite, which competes with naturally occurring thymidine triphosphate for viral DNA elongation. The incorporation of telbivudine into the viral DNA terminates viral DNA chain elongation (Kim et al., 2006). In contrast to other nucleoside analogue, such as lamivudine, telbivudine preferentially inhibits anticomplement or second-strand DNA, whereas lamivudine triphosphate preferentially inhibits the complement DNA synthesis.

Preliminary studies have shown a potent inhibition of HBV replication with a safe profile and no effect on mitochondrial metabolism. Telbivudine triphosphate does not inhibit human cellular polymerase α , β , or γ . In addition, telbivudine triphosphate is not a substrate for human DNA polymerase and thus will not induce genotoxicity.

Telbivudine is rapidly absorbed after oral dosing with peak plasma concentration achieved within 1–3 h, the absolute oral bioavailability of telbivudine is not known. Over an 8-h period, telbivudine exhibits an apparent single-phase decline, with $T_{1/2}$ of 2.5–5 h. However, a presence of a second, slower elimination phase was observed with intensive sampling in healthy volunteers up to 168 h post-dosing. The second phase starts approximately 16–24 h after dosing, with a long observed terminal-phase $T_{1/2}$ of approximately 40 h. The long plasma $T_{1/2}$ of telbivudine is consistent with the long intracellular $T_{1/2}$ (14 h) of its triphosphate *in vitro* studies. The elimination $T_{1/2}$ of telbivudine increases with renal dysfunction, therefore, dosage reduction of telbivudine is recommended in individuals with renal dysfunction.

Clinical indications

Telbivudine was approved in October 2006 by the FDA for treatment of chronic HBV infection. In clinical trials with primary end point of therapeutic response (a composite of suppression of HBV DNA and either loss of serum HBeAg or ALT normalization) after one year, in HBeAg-positive patients a therapeutic response occurred in 75% of patients treated with telbivudine and 67% of those treated with lamivudine (Lai et al., 2005). In HBeAg-negative patients, the response was 75 and 77% for telbivudine and lamivudine, respectively. In the second year of the study, telbivudine was found to be superior to lamivudine. Using the two drugs in combination was no more effective than telbivudine monotherapy.

Resistance

HBeAg-positive, 21.6%, and HBeAg-negative, 8.6%, recipients of telbivudine had HBV DNA rebound that was associated with resistance mutations. Lamivudine-resistance HBV strains have a high level of cross resistance to telbivudine. The mutations in the RT domain of HBV associated with telbivudine resistance are M204I or M204I + L180I/V (Seifer et al., 2009).

Adverse effects

Most of the adverse effects of telbivudine reported in clinical studies were mild to moderate. The most common were elevated creatinine phosphokinase (CPK), an enzyme present in muscle tissue and a marker for the breakdown of muscle tissue, upper respiratory tract infection, fatigue, headache, abdominal pain, and cough (Lai et al., 2005; Liaw et al., 2009).

Clevudine

Clevudine was approved in South Korea and in the Philippines in 2006 and 2009, respectively, for the treatment of hepatitis B after demonstration of potent anti-hepatitis B activity in phase II and III clinical trials (Yoo et al., 2007a,b). It is likely to be licensed for hepatitis B treatment in other countries.

Chemistry, mechanism of action, and antiviral activity

Clevudine [1-(2-deoxy-2-fluoro-β-L-arabinofuranosyl) thymidine] is a nucleoside analogue of the unnatural β-L configuration with potent activity against HBV and some activity against EBV. Clevudine is efficiently phosphorylated by cellular kinases to clevudine-triphosphate in target cells. The mechanism of action is mainly inhibition of viral plus-strand DNA synthesis (Balakrishna Pai et al., 1996; Chong and Chu, 2002). Preclinical studies revealed that human cellular DNA polymerases α, β, γ, and δ could not utilize the 5'-triphosphate of clevudine as a substrate and, hence, the lack of cytotoxicity. The EC₅₀ of clevudine for HBV inhibition values ranges from 0.02 to 0.84 μmol l⁻¹. Clevudine is well absorbed after oral administration with estimated long half-life of 44–60 h.

Clinical indications

Clevudine is approved for treatment of chronic hepatitis B infection in South Korea and in the Philippines. In a randomized, placebo-controlled phase III study in South Korea, chronic HBeAg-positive patients who received 30 mg of clevudine once daily for 24 weeks maintained a 3.73 log₁₀ and 2.02 log₁₀ viral suppression at 34 and 48 weeks, respectively. A unique characteristic of clevudine is the slow rebound of viremia after cessation of treatment.

Resistance

In vitro studies suggest that there may be cross-resistance with lamivudine-resistant HBV mutants. The A181T mutation, which is associated with resistance to lamivudine and adefovir, was selected for after 24 weeks of clevudine treatment (Yoo et al., 2007a).

Adverse effects

In clinical trials, clevudine was well tolerated without any serious adverse events reported. However, further development of clevudine is on hold due to associated severe myopathy and mitochondrial toxicity occurring several months after cessation of clevudine treatment in patients (Kim et al., 2009; Seok et al., 2009).

Tenofovir disoproxil fumarate

Chemistry, mechanism of action, and antiviral activity

The chemistry and mechanism of action of tenofovir disoproxil fumarate have been described in section 'tenofovir disoproxil fumarate' under 'Anti-HIV Agents.' Tenofovir has significant activity *in vitro* against both HIV-1 and HBV. Tenofovir was approved by the FDA for the treatment of HIV in 2001 and for the treatment of chronic HBV infection in 2008.

Clinical indications

Tenofovir is given orally at 300 mg day⁻¹ (one 300 mg tablet once a day) for the treatment of HBV infection. It is effective against both wild type and lamivudine-resistant HBV strains. Tenofovir is more potent than adefovir dipivoxil in the treatment of HBV infection (Del Poggio et al., 2007; Tan et al., 2008).

Adverse effects

In HIV-infected patients treated with tenofovir, there have been reports of nephrotoxicity, bone mineral density loss, and osteomalacia (Gafni et al., 2006; Grund et al., 2009; Lee and Marosok, 2003). Therefore, monitoring of both renal and non-renal adverse effects of tenofovir in HBV patients is essential.

Boceprevir

Chemistry, mechanism of action, and antiviral activity

Boceprevir [(1R,5S)-N-[3-amino-1-(cyclobutylmethyl)-2,3-dioxopropyl]-3-[2(S)-[[[(1,1-dimethylethyl)amino]carbonyl]amino]-3,3-dimethyl-1-oxobutyl]-6,6-dimethyl-3-azabicyclo[3.1.0]hexan-2(S)-carboxamide] is a linear peptidomimetic keto-amide serine protease inhibitor that binds reversibly to the HCV nonstructural 3 (NS3) active site (Venkatraman et al., 2006). Boceprevir has good binding ($K_i = 14$ nM) and cellular activity ($EC_{50} = 350$ nM) (Venkatraman, 2012). In an HCV replicon model, treatment with boceprevir resulted in 2 and 4 log₁₀ reduction in HCV RNA by 72 h and 15 days, respectively (Malcolm et al., 2006). In the initial phase I trial, combination of peginterferon with boceprevir resulted in the greatest reduction in HCV RNA and was additive (Sarrazin et al., 2007). There was no drug-drug interaction; the area under the curve (AUC) for each drug was comparable to AUC of each drug when given alone.

Bioavailability in animals ranges from 12 to 37%, indicating incomplete absorption. However, boceprevir displayed a rather high liver/plasma average ratio of 30 in rats, indicating good uptake by the target tissue. Boceprevir is metabolized primarily by aldo-keto reductase (AKR); it is reduced from ketoamide to hydroxyl amide, which is less active (Venkatraman, 2012). In addition, it undergoes oxidative metabolism by the CYP 3A4/5 enzymes to a lesser extent.

Clinical indications

Boceprevir was approved by the FDA in 2011 as the first direct-acting antiviral drug against HCV genotype 1. Boceprevir is administered in combination with peginterferon alfa and ribavirin; the dose of boceprevir is 800 mg three times a day with food. Therapy with peginterferon alfa and ribavirin for 4 weeks (lead-in period) is recommended before adding boceprevir; this is based on results from clinical trials. The lead-in period allows peginterferon and ribavirin to reach steady-state concentrations to avoid a period of functional monotherapy with boceprevir and reduce the development of drug resistance HCV (Kwo, 2012; Poordad et al., 2011). A response-guided duration of therapy is recommended. If HCV RNA levels are undetectable at weeks 8 and 24, patients may be treated with triple therapy (boceprevir, peginterferon and ribavirin) for 28 weeks. If HCV RNA is detected at week 8 and undetected at week 24, then the triple therapy should continue for 36 weeks followed by a 12-week combination of peginterferon and ribavirin tail for a total of 48 weeks of therapy (Kwo, 2012).

Resistance

In vitro resistance mutation selection for boceprevir in replicon cells revealed the following mutations – A156S/T, R155K, T54S, and V36M (Tong et al., 2006). Population sequencing of the NS3 domain of isolates from the clinical trials revealed major mutations (V36M, T54S, and R155K) and minor mutations (T54A, V55A, R155T, A156S, V158I, and V170A) (Kwo, 2012).

Adverse effects

The most commonly reported adverse effects were fatigue, anemia, nausea, headache, and dysgeusia when boceprevir was used in combination with peginterferon and ribavirin (Poordad et al., 2011).

Telaprevir

Chemistry, mechanism of action, and antiviral activity

Telaprevir ((1*S*,3*aR*,6*aS*)-2-[(2*S*)-2-[(2*S*)-2-cyclohexyl-2-[(pyrazin-2-ylcarbonyl)amino]acetyl]amino]-3,3-dimethylbutanoyl]-*N*-[(3*S*)-1-(cyclopropylamino)-1,2-dioxohexan-3-yl]-3,3*a*,4,5,6,6*a*-hexahydro-1*H*-cyclopenta[*c*]pyrrole-1-carboxamide) is a reversible HCV NS3/4A protease inhibitor; an example of direct-acting antiviral agents (DAAs) for the treatment of HCV (Perni et al., 2006). Telaprevir first binds weakly to the NS3/4A protease and then forms a covalent bond between the hydroxyl group of the catalytic serine and the keto-carbonyl group of telaprevir. The $T_{1/2}$ dissociation of this complex is 58 min. Telaprevir is selective for HCV NS3/4A and does not inhibit other serine proteases.

Telaprevir is readily absorbed orally with a T_{max} between 2.5 and 5.0 h (Foster et al., 2011). The C_{max} , C_{min} , and AUC for telaprevir are higher when telaprevir is given in combination with peginterferon and ribavirin than when given as monotherapy. A high-fat breakfast increased the the AUC by about 20% compared with a standardized meal (Matthews and Lancaster, 2012). Telaprevir is metabolized in the liver through reduction, hydrolysis, and oxidation. Telaprevir is a substrate and an inhibitor of CYP 3A4 isozyme. Telaprevir is both a substrate and an inhibitor of P-glycoprotein. Agents that induce CYP 3A4 or P-glycoprotein may reduce plasma concentration of telaprevir. Telaprevir is eliminated mainly through the feces and to some extent through expired air and urine.

Clinical indications

Telaprevir was approved in May 2011 by the FDA for treatment of HCV genotype 1 infected patients based on its efficacy and tolerability in clinical trials (McHutchison et al., 2010; Zeuzem et al., 2011). Telaprevir is administered in combination with peginterferon and ribavirin. The recommended dosage of telaprevir is 750 mg 3 times a day. A respond-guided duration of treatment is recommended for telaprevir combination therapy. The recommended duration of treatment with telaprevir is 12 weeks in combination with peginterferon and ribavirin. HCV RNA levels should be monitored at weeks 4 and 12 to determine combination treatment duration and assess for treatment futility. Recommendations for treatment-naïve and patients with relapse of infection: (1) if HCV RNA is undetectable at week 4, triple therapy (telaprevir/peginterferon/ribavirin) is given for 12 weeks and an additional 12 weeks of dual therapy (peginterferon/ribavirin) for a total of 24 weeks of therapy; and (2) if HCV RNA is detectable at weeks 4 and/or 12, triple therapy (telaprevir/peginterferon/ribavirin) is given for 12 weeks and an additional 36 weeks of dual therapy (peginterferon/ribavirin) for a total of 48 weeks of therapy. For prior partial and null responder patients, triple therapy (telaprevir/peginterferon/ribavirin) is given for 12 weeks and an additional 36 weeks of dual therapy (peginterferon/ribavirin) for a total of 48 weeks of therapy.

Resistance

Mutations associated with telaprevir resistance are: minor mutations, conferring low level resistance, (V36A/M/L, T54S/A, R155K, and A156V/T) and major mutations, conferring high level resistance, (V23A+V36M, and V36M+R155K).

Adverse effects

In clinical trials, the prevalence of adverse effects commonly associated with telaprevir in combination with peginterferon/ribavirin versus peginterferon/ribavirin were rash (56% vs 34%); pruritus (47% vs 28%); nausea (39% vs 28%); diarrhea (26% vs 17%) and anemia (36% vs 17%) (Hezode et al., 2009; McHutchison et al., 2010).

Simeprevir

Chemistry, mechanism of action, and antiviral activity

Simeprevir ((2*R*,3*aR*,10*Z*,11*aS*,12*aR*,14*aR*)-*N*-(cyclopropylsulfonfyl)-2-[[2-(4-isopropyl-1,3-thiazol-2-yl)-7-methoxy-8-methyl-4-quinolinyl]oxy]-5-methyl-4,14-dioxo-2,3,3*a*,4,5,6,7,8,9,11*a*,12,13,14,14-tetradecahydrocyclopenta[*c*]cyclopropa[*g*] [1,6]diazacyclotetradecine-12*a*(1*H*)-carboxamide) is an HCV NS3/4A protease inhibitor, a direct-acting antiviral agent, for the treatment of chronic HCV infection. The K_i value of simeprevir on HCV NS3/4A protease of genotypes 1*a* and 1*b* was 0.5 and 1.4 nM, respectively (Lin et al., 2009; Rosenquist et al., 2014). Simeprevir is highly selective (>1000-fold) for NS3/4A versus most of the evaluated human proteases. *In vitro* combination studies of simeprevir with interferon, ribavirin, NS5A or NS5B inhibitors resulted in additive or synergistic effects (54.) Simeprevir has activity against HCV genotypes 1, 2, 4, 5, and 6. In combination with ribavirin and interferon, simeprevir showed additive and synergistic effects, respectively (Lin et al., 2009).

The PK profile of simeprevir varied in different animals. In dogs, simeprevir achieved 100% bioavailability after oral administration of 6.5 mg kg⁻¹; with high C_{max} (4.72 μ M), AUC (14 986 ng·h ml⁻¹), and a long half-life ($T_{1/2}$ = 5.1 h) (Rosenquist et al., 2014). After oral administration in rats, simeprevir was well distributed with a high concentration observed in the liver and with a liver/plasma ratio of 32. Achieving high drug concentrations in the liver is critical for HCV DAAs given that viral replication of HCV occurs almost exclusively in hepatocytes. Simeprevir binds extensively to plasma proteins (>99%). However, only a 2.4-fold shift of the replicon EC₅₀ value was observed with the addition of 50% human serum albumin. Simeprevir inhibits CYP3A4 and P-glycoprotein; with a potential for drug-drug interaction.

Clinical indications

Simeprevir was approved in November 2013 by the FDA for treatment of chronic HCV infected patients. The recommended dose of simeprevir is 150 mg once a day administered in combination with peginterferon and ribavirin. All treatment-naïve and prior relapser patients, including those with cirrhosis, should receive an additional 12 weeks of peginterferon alfa and ribavirin after completing 12 weeks of treatment with simeprevir, peginterferon alfa and ribavirin (total treatment duration of 24 weeks). All prior non-responder patients, including those with cirrhosis, should receive an additional 36 weeks of peginterferon alfa and ribavirin after completing 12 weeks of treatment with simeprevir, peginterferon alfa and ribavirin (total treatment duration of 48 weeks).

Resistance

In vitro drug resistance selection studies revealed that mutations at the NS3 positions 43, 80, 155, 156 and 168, either alone or in combination conferred varying degrees of resistance to simeprevir (Lenz et al., 2010). In clinical trials, patients with breakthrough viremia or relapse had the D168V mutation alone or in combination with other NS3 mutations HCV (Izumi et al., 2014).

Adverse effects

The most common adverse effects were headache, fatigue, pyrexia, and influenza-like illness; these were similar in the simeprevir and placebo arms. However, rash and photosensitivity reactions were higher in the simeprevir arm (Manns et al., 2014).

Sofosbuvir

Chemistry, mechanism of action, and antiviral activity

Sofosbuvir ((S)-Isopropyl 2-((S)-(((2R,3R,4R,5R)-5-(2,4-dioxo-3,4-dihydropyrimidin-1(2H)-yl)-4-fluoro-3-hydroxy-4-methyltetrahydrofuran-2-yl)methoxy)-(phenoxy)phosphorylamino)propanoate) is a nucleotide analogue NS5B polymerase inhibitor and a direct-acting antiviral agent against the hepatitis C. Sofosbuvir is phosphorylated by host cellular kinases to a uridine triphosphate analogue, which is responsible for its antiviral activity.

Following oral administration of sofosbuvir, the peak plasma concentration was observed at 0.5–2 h post-dose, regardless of dose level. Based on population pharmacokinetic analysis in subjects with genotype 1–6 HCV infection who were coadministered ribavirin (with or without pegylated interferon), geometric mean steady state AUC_{0-24} of sofosbuvir and GS-331007 (predominant circulating metabolite of sofosbuvir) were $828 \text{ ng} \cdot \text{h ml}^{-1}$ and $6790 \text{ ng} \cdot \text{h ml}^{-1}$, respectively. Sofosbuvir is approximately 61–65% bound to human plasma proteins and the binding is independent of drug concentration over the range of $1\text{--}20 \text{ } \mu\text{g ml}^{-1}$. It is renally eliminated via glomerular filtration and active tubular secretion as the metabolite GS-331007, with a median $T_{1/2}$ of 0.48–0.75 h (Rodriguez-Torres et al., 2013). Sofosbuvir is a substrate of P-glycoprotein and breast cancer resistance protein (BRCP) drug transporters. Sofosbuvir is not metabolized by cytochrome P450 (CYP) isoenzymes, nor does it induce or inhibit the metabolism of agents that are substrates of these enzymes.

Clinical indications

Sofosbuvir was approved in December 2013 by the FDA for treatment of chronic HCV infected patients. It is recommended for use in combination with ribavirin for genotypes 2 and 3 infections or in combination with peginterferon and ribavirin for genotypes 1 and 4 infections. The recommended dose of sofosbuvir is 400 mg once daily in combination with ribavirin or ribavirin and peginterferon. The recommended regime and treatment duration is: for patients with HCV genotype 1 or 4, sofosbuvir is given with peginterferon and ribavirin for 12 weeks; for genotype 2 patients, sofosbuvir in combination with ribavirin for 12 weeks; and for genotype 3 patients, sofosbuvir in combination with ribavirin for 24 weeks.

Resistance

Sofosbuvir has a high barrier to resistance. *In vitro* drug resistance selection studies revealed that S282T mutation could reduce susceptibility to sofosbuvir. Subsequently, V321A and L159F mutations have been observed in minority of patients receiving sofosbuvir treatment during clinical trials (Zeuzem et al., 2014). The clinical significance of these mutations is not known.

Adverse effects

The most common adverse effects when sofosbuvir was given in combination with peginterferon and ribavirin were fatigue, headache, nausea, insomnia, and anemia.

Future Prospects

Current antiviral agents either inhibit hepatitis B replication, or invoke an immune response, which may be necessary but not sufficient to effect viral control (Dusheiko and Antonakopoulos, 2008). Moreover, antiviral resistance remains a concern with long-term therapy, the search for novel agents, and treatment strategies with minimal or no resistance and good long-term safety profile are the focus of ongoing research (Cheng et al., 2005). Emtricitabine, licensed for the treatment of HIV infections, also has activity against HBV, but are not yet FDA-approved for this indication. There are a number of new nucleoside and nucleotide analogue in the pipeline; elvicitabine, valtorcitabine, amdoxovir, racivir, MIV 210, β -L-FddC, alamifovir and heparivir B may soon be part of the armamentarium for hepatitis B treatment. Another challenge is the management of hepatitis B in individuals with HIV coinfection. Appropriate combination regimens for individuals with coinfections are expected in the near future; target treatment of HBV to alter the outcome and take into account the impact of HBV treatment on HIV.

The last decade has ushered in unparalleled advances in the treatment of HCV. The advent of DAAs has provided highly effective, well tolerated and shorter duration of HCV therapy. There are several next generation DAAs in clinical development that will soon make interferon-based HCV regimens a thing of the past (Afdhal et al., 2014a,b; Feld, 2014; Feld et al., 2014; Kowdley et al., 2014a,b; Poordad et al., 2014). Future goals of HCV therapy are to improve tolerability, shorten duration of therapy, discovery of agents with pan genotypic activity, overcome issues of resistance, and availability of cost-effective regimens.

Therapeutics for Papillomavirus

HPVs are small DNA viruses with strict epithelial tropism. HPV infection induces the hyperproliferation of epithelial cells, leading to a broad spectrum of human diseases, ranging from benign warts (self-limiting) to malignant neoplasms. In general, there is no virus-specific effective systemic therapy available. Furthermore, treatment of disease with current therapies has not been shown to reduce the rates of transmission.

The recently FDA-approved quadrivalent prophylactic vaccine (HPV6/11/16/18) has been shown in clinical trials to be effective in preventing high-grade vulval and vaginal lesion associated with HPV 16 and 18. With time, this prophylactic vaccine is expected to reduce the incidence of HPV infections, particularly, infections due to the vaccine types (HPV6, 11, 16, and 18).

Interferon

IFNs have antiproliferative, antiviral, and immunomodulatory properties. IFNs have been administered (mostly IFN- α) topically, systemically, and intralesionally with variable results. They are more effective if used in combination with either local surgery or podophyllotoxin. Several large controlled trials have demonstrated inconsistent clinical benefits of the use of standard IFN- α therapy of condyloma acuminatum (caused by HPV) that was refractory to cytoreductive therapies. Intralesional therapy is painful, systemic therapy is associated with influenza-like symptoms such as fever and myalgia. Furthermore, IFN treatment is expensive and there is limited efficacy.

Imiquimod

This is an immunomodulator approved by the FDA for topical treatment of external and perianal genital warts. It acts as a ligand for Toll-like receptor 7 and activates macrophage and dendritic cells to release IFN α and other proinflammatory cytokines. With imiquimod application, gradual clearance of warts occurs in about 50% of patients over an average of 8–10 weeks. The adverse effects are; application site reactions (irritation, pruritus, flaking, and erosion), and systemic effects including fatigue and influenza-like illness.

Podophyllotoxin

Podophyllotoxin is the main cytotoxic ingredient of podophyllin, a resin used for many years for topical treatment of warts. The exact mechanism of action is unknown. Podophyllotoxin 0.5% solution or gel is similar in effectiveness to imiquimod but may have more adverse effects. Adverse effects include irritation of the adjacent skin, local erosion, ulceration and scarring.

Trichloroacetic acid, podophyllotoxin, and cryotherapy (with liquid nitrogen or a cryprobe) remain the most widely used treatments for external genital warts, but response rate is only 60–70%, and at least 20–30% of responders will have recurrence.

Future Prospects

The current therapies are not targeted antiviral therapies. They result in the physical removal of the lesion or the induction of nonspecific inflammation, thereby inducing a bystander immune response. There is urgent need to develop specific and effective antiviral agents for HPV infections.

Therapeutics for Enteroviral Infections

The enteroviruses include nearly 70 serotypes of closely related pathogens that cause a wide spectrum of human illness, from mild nonspecific fever to common upper respiratory infections, aseptic meningitis, severe myocarditis, encephalitis, and paralytic poliomyelitis. Certain patients, including antibody-deficient individuals, bone marrow recipients, and neonates, may develop potentially life-threatening enterovirus infections for which therapeutic options have been limited. There are case series of the use of immune serum globulin and pleconaril for serious enteroviral infections. Pleconaril failed to secure FDA approval because of its induction of CYP 3A enzyme activity, and the potential for drug interactions, particularly the interference with oral contraceptives.

Pleconaril

Chemistry, mechanism of action, and antiviral activity

Pleconaril (3-(Poordad et al., 2011)propyl]phenyl]-5[trifluoromethyl]-1,2,4-oxadiazole) exerts its antiviral effect by integrating into a hydrophobic pocket inside the virion, and prevents viral replication by inhibiting viral uncoating and blocking viral attachment to host cell receptors, thus interrupting the infection cycle. The viral capsid structure, which is the target of pleconaril, is relatively conserved among the picornaviruses. Pleconaril has broad spectrum and potent activity against enteroviruses and rhinoviruses.

Pleconaril is 70% bioavailability when given orally. This high level of bioavailability was achieved by the substitution of trifluoromethyl on the oxadiazole ring that reduces its degradation in the liver by enzymes involved in oxidative processes. The metabolic stabilization is reflected in the drug's long serum half-life (about 6.5 h) after oral dosing. Pleconaril also readily penetrates the blood–brain barrier.

Clinical indications

Common cold

In a phase I trial of pleconaril for treatment of common cold, there was a significant reduction in rhinorrhea of about 1.5 days in those on 400 mg three times daily, and a reduction in a severity score as compared to the placebo. Subsequent trials confirmed a modest reduction in length of symptoms for common cold in patients treated with pleconaril (Hayden et al., 2003).

Immunocompromised host

Patients with compromised humoral immunity, such as those with agammaglobulinemia, who contract enteroviral infections may develop chronic meningitis and meningoencephalitis, often with a fatal outcome. There are case reports of the efficacy of pleconaril in these patients.

Enteroviral meningitis

For treatment of enteroviral meningitis, two large studies showed a marginal statistical improvement in a clinical score in the pleconaril-treated groups (Desmond et al., 2006). A subsequent small study of 21 infants with proven enteroviral meningitis in the United States did not have enough power to show unequivocal benefit with pleconaril (Abzug et al., 2003).

Resistance

Resistance to pleconaril has been reported in some serotypes of enteroviruses, however, the mechanism is not well understood.

Adverse effects

Pleconaril is generally well tolerated. The most common adverse events are headache, diarrhea, and nausea. Long-term use of pleconaril is associated with an increase in menstrual irregularities in women.

Future Prospects

Pleconaril has not been licensed for treatment of enteroviral infections; there is an urgent need to identify alternative drugs that might be effective. There are several investigational compounds; however, none has reached phase I clinical trial. Combinations of drugs are likely to offer the best chance of cure and protection from enterovirus infections in the future.

Anti-HIV Agents

The combination of three or more anti-HIV agents into multidrug regimens, often termed highly active antiretroviral therapy (HAART), can efficiently inhibit HIV viral replication to achieve low or undetectable circulatory HIV-1 levels. This is the start-of-the-art treatment of AIDS or HIV-infected individuals. Drug combinations are, in principle, aimed at obtaining synergism between the compounds, while reducing the likelihood of the development of drug resistance virus, and minimizing toxicity. The available anti-HIV drugs are categorized according the step they target within the HIV viral life cycle (Figure 2); (1) binding inhibitors, for example, coreceptor antagonist (maraviroc); (2) fusion inhibitors (enfuvirtide); (3) reverse transcriptase inhibitors (nucleoside/nucleotide (zidovudine,

Figure 2 HIV life cycle showing the stages of intervention of available anti-HIV agents.

didanosine, zalcitabine, stavudine, lamivudine, abacavir, emtricitabine, and tenofovir), and non-nucleoside (nevirapine, delavirdine, and efavirenz) analogue); (4) integrase inhibitors (raltegravir); and (5) protease inhibitors (saquinavir, indinavir, ritonavir, nelfinavir, amprenavir, fosamprenavir, lopinavir, atazanavir, tipranavir, and darunavir).

Fixed-dose combinations and once-daily dosage forms of many anti-HIV agents are available. There are fixed-dose combinations for zidovudine/lamivudine, zidovudine/lamivudine/abacavir, abacavir/lamivudine, tenofovir/emtricitabine, and tenofovir/emtricitabine/efavirenz.

Coreceptor Antagonist

Maraviroc

Chemistry, mechanism of action, and antiviral activity

Maraviroc (4,4-difluoro-*N*-{(1*S*)-3-[*exo*-3-(3-isopropyl-5-methyl-4*H*-1,2,4-triazol-4-yl)-8-azabicyclo(3,2,1]oct-8-yl]-1-phenylpropyl}cyclohexanecarboxamide) is the first of the class of CCR5 coreceptor antagonists licensed (August 2007) for HIV treatment. Maraviroc selectively binds to the human chemokine receptor CCR5 present on the cell membrane, preventing the interaction of HIV-1 gp120 and CCR5 necessary for CCR5-tropic HIV-1 to enter cells. It inhibits the replication of CCR5-tropic laboratory strains and primary isolates of HIV-1 *in vitro*. The mean EC₅₀ for maraviroc against various strains of HIV-1 ranges from 0.1 to 1.25 nmol l⁻¹ (0.05–0.64 ng ml⁻¹) in cell culture. Maraviroc was not active against CXCR4-tropic and dual-tropic viruses (EC₅₀ value >10 μmol l⁻¹). The antiviral activity of maraviroc against HIV-2 has not been evaluated.

The absolute bioavailability for 100 and 300 mg doses are 23 and 33%, respectively. Peak plasma concentrations of maraviroc are attained at 0.5–4 h following single oral dose of 1200 mg administered to uninfected volunteers. Maraviroc is bound (approximately 76%) to human plasma proteins. It is principally metabolized by the cytochrome P450 system to metabolites that are essentially inactive against HIV-1. Maraviroc is a substrate of CYP3A and the efflux transporter P-glycoprotein (Pgp), and therefore, its pharmacokinetics are likely to be modulated by inhibitors and inducers of these enzymes/transporters. The terminal half-life in healthy subjects is 14–18 h.

Clinical indications

Maraviroc is approved for use in combination with other anti-HIV agents for the treatment of adults with CCR5-tropic HIV-1, who are treatment-experienced with evidence of viral replication and HIV-1 strains resistant to multiple antiretroviral agents.

Resistance

The resistance profile in treatment-naïve and treatment-experienced subjects has not been fully characterized. HIV-1 variants with reduced susceptibility to maraviroc have been selected in cell culture, following serial passage of two CCR5-tropic viruses (CC1/85 and RU570). The maraviroc resistant viruses remained CCR5-tropic with no evidence of a change from a CCR5-tropic virus to a CXCR4-using virus. Two amino acid residue substitutions (Table 1, letter codes of amino acids) in the V3-loop region of the HIV-1 envelope glycoprotein (gp160), A316T and I323V were shown to be necessary for the maraviroc-resistant phenotype in the HIV-1 isolate CC1/85. In the RU570 isolate, a 3-amino acid residue deletion in the V3 loop, ΔQAI (HXB2 positions 315–317), was associated with maraviroc resistance. The clinical relevance of these mutations is not known.

Adverse effects

The most common adverse events reported with maraviroc were cough, fever, upper respiratory tract infections, rash, musculoskeletal symptoms, abdominal pain, and dizziness. The product label includes a warning about liver toxicity (hepatotoxicity) and a statement about the possibility of heart attacks.

Table 1 The three-letter and one-letter codes for amino acid residues

Amino acid	Three-letter code	One-letter code
Alanine	Ala	A
Arginine	Arg	R
Asparagine	Asn	N
Aspartic acid	Asp	D
Cysteine	Cys	C
Glutamic acid	Glu	E
Glutamine	Gln	Q
Glycine	Gly	G
Histidine	His	H
Isoleucine	Ile	I
Leucine	Leu	L
Lysine	Lys	K
Methionine	Met	M
Phenylalanine	Phe	F
Proline	Pro	P
Serine	Ser	S
Threonine	Thr	T
Tryptophan	Trp	W
Tyrosine	Tyr	Y
Valine	Val	V

Fusion Inhibitors

Enfuvirtide

Chemistry, mechanism of action, and antiviral activity

Enfuvirtide, a linear 36-amino acid synthetic peptide with the N-terminus acetylated and the C-terminus is a carboxamide, is the first licensed agent in the class of fusion inhibitors. Enfuvirtide interferes with the entry of HIV-1 into cells by inhibiting fusion of viral and cellular membranes (Figure 2). Enfuvirtide binds to the first heptad-repeat (HR1) in the gp41 subunit of the viral envelope glycoprotein and prevents the conformational changes required for the fusion of viral and cellular membranes. The IC_{50} of enfuvirtide for baseline clinical isolates ranged from 0.089 to 107 $nmol\ l^{-1}$ (0.4–480 $ng\ ml^{-1}$). Enfuvirtide is active against R5, X4, and dual tropic viruses, but has no activity against HIV-2.

Enfuvirtide is administered twice daily by subcutaneous injection. Single-dose vials contain 108 mg of enfuvirtide for the delivery of approximately 90 $mg\ ml^{-1}$ when reconstituted. The absolute bioavailability is $84.3 \pm 15.5\%$. Following 90 mg bid dosing of enfuvirtide subcutaneously in combination with other antiretroviral agents in HIV-1 infected subjects, the median T_{max} was 4 h (ranged from 4 to 8 h). Enfuvirtide is catabolized by proteolytic enzymes. It is not metabolized by hepatic CYP450 isoenzyme systems. There are no known clinically significant interactions between enfuvirtide and other medications.

Clinical indications

Enfuvirtide was approved by the FDA in March 2003 for use in adults, and in children aged 6 and older, with advanced HIV infection. Enfuvirtide is used with other anti-HIV agents to treat HIV-1 infection in patients who are treatment-experienced and have detectable viral loads even though they are taking anti-HIV agents.

Resistance

HIV-1 isolates with reduced susceptibility to enfuvirtide have been selected *in vitro*. Genotypic analysis of these resistant isolates showed mutations that resulted in amino acid substitutions at the enfuvirtide binding HR1 domain positions 36–38 of the HIV-1 envelope glycoprotein gp41. In clinical trials, HIV-1 isolates with reduced susceptibility to enfuvirtide have been recovered from subjects failing enfuvirtide-containing regimen. Most of the isolates with decreased in susceptibility to enfuvirtide of greater than fourfold exhibited genotypic changes in the codons encoding gp41 HR1 domain amino acids 36–45.

HIV-1 clinical isolates resistant to nucleoside analogue reverse transcriptase inhibitors, non-nucleoside analogue reverse transcriptase inhibitors, and protease inhibitors are susceptible to enfuvirtide in cell culture.

Adverse effects

The most common adverse effects of enfuvirtide are injection site reactions. Other symptomatic side effects may include insomnia, headache, dizziness, and nausea. Several cases of hypersensitivity have been described. In phase III studies, bacterial pneumonia was seen at a higher rate in patients who received enfuvirtide than in those who did not receive enfuvirtide. Eosinophilia is the primary laboratory abnormality seen with enfuvirtide administration.

Reverse Transcriptase Inhibitors

Nucleoside/nucleotide reverse transcriptase inhibitors

Zidovudine

Chemistry, mechanism of action, and antiviral activity

Zidovudine (3'-azido-2',3'-dideoxythymidine) is a pyrimidine analogue with an azido group substituting for the 3' hydroxyl group on the ribose ring. Zidovudine is initially phosphorylated by cellular TK and then to its diphosphate by cellular thymidylate kinase. The triphosphate derivative competitively inhibits HIV reverse transcriptase, and functions as a chain terminator. Zidovudine inhibits HIV-1 at concentrations of approximately 0.013 $\mu g\ ml^{-1}$. In addition, it inhibits a variety of other retroviruses. Synergy has been demonstrated against HIV-1 when zidovudine is combined with didanosine, zalcitabine, lamivudine, nevirapine, delavirdine,

saquinavir, indinavir, zidovudine, and other compounds. It was the first drug to be licensed for the treatment of HIV infection, and still is used in combination with other drugs as initial therapy for some patients.

Zidovudine is available in capsule, syrup, and intravenous formulations. Oral bioavailability is approximately 65%. Peak plasma levels are achieved approximately 0.5–1.5 h after treatment. Zidovudine penetrates cerebrospinal fluid, saliva, semen, and breast milk and it crosses the placenta. Drug is predominately metabolized by the liver through the enzyme uridine diphosphoglucuronosyltransferase to its major inactive metabolite 3'-azido-3'-deoxy-5'-O- β -D-glucopyranuronosylthymidine. The elimination $T_{1/2}$ is approximately 1 h; however, it is extended in individuals who have altered hepatic function.

Clinical indications

Zidovudine is used in combination with other anti-HIV agents. It is administered orally at 600 mg day⁻¹ (300 mg tablet, twice a day). The single most important usage of zidovudine in the last decade has been the peripartum three-part zidovudine regimen, which has decreased the incidence of transmission of HIV infection from pregnant women to their infants.

Adverse effects

The predominant adverse effect of zidovudine is myelosuppression, as evidenced by neutropenia and anemia, occurring in 16 and 24% of the patients, respectively. Zidovudine has been associated with skeletal and cardiac muscle toxicity, including polymyositis. Nausea, headache, malaise, insomnia, and fatigue are common side effects.

Didanosine

Chemistry, mechanism of action, and antiviral activity

Didanosine (2',3'-dideoxyinosine) is a purine nucleoside with inhibitory activity against both HIV-1 and HIV-2. Didanosine is activated by intracellular phosphorylation. It is first converted to 2',3'-dideoxyinosine-5'-monophosphate by 5' nucleotidase and inosine 5'-monophosphate phosphotransferase and subsequently to 2', 3'-dideoxyadenosine-5'-monophosphate by adenylosuccinate synthetase and lyase. It is then converted to diphosphate by adenylate kinase and subsequently by creatine kinase or phosphoribosyl pyrophosphate synthetase to the triphosphate. The triphosphate metabolite is a competitive inhibitor of HIV reverse transcriptase and a chain terminator. The spectrum of activity of didanosine is enhanced by synergism with zidovudine and stavudine as well as the protease inhibitors.

Didanosine is acid labile and has poor solubility. A buffered tablet results in 20–25% bioavailability. A 300 mg oral dose achieves peak plasma concentrations of 0.5–2.6 $\mu\text{g ml}^{-1}$ with a $T_{1/2}$ of approximately 1.5 h. It is metabolized to hypoxanthine and is cleared primarily by the kidneys.

Clinical indications

Didanosine is used in combination with other anti-HIV agents as part of HAART. It is given as two 100 mg tablets (buffered tablets) twice a day or as one 400 mg capsule (delayed-release capsule) once a day.

Adverse effects

The most significant adverse effect associated with didanosine therapy is the development of peripheral neuropathy (30%) and pancreatitis (10%). Lipoatrophy, lactic acidosis and diabetes have been observed in patients on antiretroviral regimens containing didanosine.

Zalcitabine

Chemistry, mechanism of action, and antiviral activity

Zalcitabine (2',3'-dideoxycytidine) is a pyrimidine analogue, which is activated by cellular enzymes to its triphosphate derivative. The enzymes responsible for activation of zalcitabine are cell cycle independent, and therefore this offers a theoretical advantage for nondividing cells, specifically dendritic and monocyte/macrophage cells. Zalcitabine inhibits both HIV-1 and HIV-2 at concentrations of approximately $0.03 \mu\text{mol l}^{-1}$.

The oral bioavailability following zalcitabine administration is more than 80%. The peak plasma concentrations following an oral dose of 0.03 mg kg^{-1} range from 0.1 to $0.2 \mu\text{mol l}^{-1}$ and the $T_{1/2}$ is approximately 20 min. The drug is cleared mainly by the kidneys, and therefore, the presence of renal insufficiency leads to a prolonged plasma $T_{1/2}$.

Clinical indications

Zalcitabine is used as part of HAART regimen for HIV-1 infections. It is administered orally at 2.25 mg day^{-1} (one 0.75 mg tablet every 8 h).

Adverse effects

Peripheral neuropathy is the major toxicity associated with zalcitabine administration, occurring in approximately 35% of individuals. Pancreatitis can occur, but does so infrequently. Thrombocytopenia and neutropenia are uncommon (5% and 10%, respectively). Other zalcitabine-related side effects include nausea, vomiting, headache, hepatotoxicity, and cardiomyopathy.

Stavudine

Chemistry, mechanism of action, and antiviral activity

Stavudine (2',3'-didehydro, 3'-deoxythymidine) is a thymidine analogue with significant activity against HIV-1, having inhibitory concentrations, which range from 0.01 to $4.1 \mu\text{mol l}^{-1}$. Its mechanism of action is similar to that of zidovudine.

The oral bioavailability of stavudine is more than 85%. Peak plasma concentrations of approximately $1.2 \mu\text{g ml}^{-1}$ are reached within 1 h of dosing at 0.67 mg kg^{-1} per dose. Stavudine penetrates CSF and breast milk. It is excreted by the kidneys unchanged and, in part, by renal tubular secretion.

Clinical indications

Stavudine is used for HIV infection in combination with other anti-HIV agents. Stavudine is a highly potent inhibitor of HIV-1 replication *in vitro*. However, its use has been limited by delayed toxicity, notably peripheral neuropathy and myopathy caused by mitochondrial damage. It is administered orally at 80 mg day^{-1} (one 40 mg capsule every 12 h).

Adverse effects

The principal adverse effect of stavudine therapy is the development of peripheral neuropathy. The development of this complication is related to both dose and duration of therapy. Inhibition of mitochondrial DNA synthesis is proposed to induce depletion of cellular mitochondrial DNA and it is ultimately responsible for the delayed toxicity observed with the use of stavudine and other nucleoside reverse transcriptase inhibitors (NRTIs). Neuropathy tends to appear after 3 months of therapy and resolves slowly with medication discontinuation. Other side effects are uncommon. Fatal and nonfatal pancreatitis have occurred during therapy when stavudine was part of a combination regimen that included didanosine. Redistribution and accumulation of body fat (lipodystrophy) have been observed in patients receiving stavudine as part of their antiretroviral regimen.

Lamivudine

Chemistry, mechanism of action, and antiviral activity

The chemistry and mechanism of action of lamivudine have been described previously in section 'Lamivudine' under 'Therapeutics for Hepatitis.' Lamivudine has significant activity *in vitro* against both HIV-1 and HIV-2, as well as HBV. Lamivudine is a competitive inhibitor of the viral reverse transcriptase.

Clinical indications

Lamivudine is used in combination with other anti-HIV agents. Lamivudine is given orally at 300 mg day^{-1} (one 150 mg tablet twice a day, or one 300 mg tablet once a day). It is also formulated in combination with zidovudine, or with zidovudine and abacavir as fixed-dose combination tablet.

Adverse effects

Lamivudine has an extremely favorable toxicity profile. This may largely be attributed to the low affinity of lamivudine for human DNA polymerases, and the lack of active lamivudine metabolites in the mitochondrial compartment of cells. At the highest doses of $20 \text{ mg kg}^{-1} \text{ day}^{-1}$, neutropenia is encountered but at a low frequency. In pediatric studies, pancreatitis and peripheral neuropathies have been reported.

Abacavir

Chemistry, mechanism of action, and antiviral activity

Abacavir sulfate, (1*S*,4*R*)-4-[2-amino-6-(cyclopropylamino)-9*H*-purin-9-yl]-2-cyclopentene-1-methanol, is a structural analogue of the purine guanine. The phosphorylation pathway of abacavir differs from that of all other nucleoside analogues. The first step in the conversion of abacavir to its active metabolite, carbovir triphosphate, is phosphorylation to abacavir monophosphate by adenosine phosphotransferase. This step is followed by deamination by a cytosolic enzyme to form carbovir monophosphate, which undergoes two subsequent phosphorylations, to the diphosphate by guanylate kinase and to the triphosphate by nucleoside diphosphate kinase and other enzymes. Carbovir triphosphate competes with endogenous 2'-dGTP for incorporation into the nucleic acid chain, and after incorporation, terminates DNA chain elongation. Abacavir exhibits potent *in vitro* antiviral activity against wild-type HIV-1 ($\text{IC}_{50} \ 4.0 \ \mu\text{mol l}^{-1}$), but this activity is lower than the activity of zidovudine ($\text{IC}_{50} \ 0.040 \ \mu\text{mol l}^{-1}$). However, there is no significant difference between the levels of activity of abacavir ($\text{IC}_{50} \ 0.26 \ \mu\text{mol l}^{-1}$) and AZT ($\text{IC}_{50} \ 0.23 \ \mu\text{mol l}^{-1}$) against clinical isolates of HIV-1.

Abacavir is well absorbed after oral administration with a bioavailability between 76 and 96%. After single or multiple doses, C_{max} is attained after a mean of 0.7–1.7 h, and the mean half-life is 0.8–1.5 h. However, at a dose of 300 mg twice daily as part of a combination regimen, levels of intracellular carbovir triphosphate ranged from <20 to 374 fmol per 10^6 cells. The intracellular carbovir triphosphate was measurable throughout the 24-h study period, with the highest levels found between 6 and 8 h. This finding suggests a long half-life for carbovir triphosphate within cells. The main route of excretion is renal.

Clinical indications

Abacavir is used in combination with other anti-HIV agents. It is given as a 300 mg tablet twice a day, or two 300 mg tablets once a day. A fixed-dose combination with lamivudine is available (600 mg abacavir, plus 300 mg lamivudine).

Adverse effects

The abacavir hypersensitivity reaction is a potentially fatal syndrome occurring in approximately 5% of HIV-infected patients exposed to this nucleoside analogue after a median of 11 days (range: 1–318 days). Systemic manifestations can include fever, rash, fatigue, and gastrointestinal or respiratory symptoms. Rechallenge with abacavir in individuals presumed to have abacavir hypersensitivity reaction is avoided due to reports of fatal reactions caused by repeated administration of abacavir following a hypersensitivity reaction. The presence of HLA-B*5701 has been associated with elevated odds of developing abacavir hypersensitivity reaction.

Emtricitabine

Chemistry, mechanism of action, and antiviral activity

Emtricitabine, 5-fluoro-1-(2*R*,5*S*)-[2-(hydroxymethyl)-1,3-oxathiolan 5-yl]cytosine, is a fluorinated nucleoside analogue of cytosine. Emtricitabine, similar in many ways to lamivudine, has *in vitro* activity against HIV-1 that is similar to or approximately fourfold to tenfold more potent than that of lamivudine. The EC_{50} for emtricitabine is in the range of 0.0013–0.64 $\mu\text{mol l}^{-1}$ (0.0003–0.158 $\mu\text{g ml}^{-1}$) for laboratory and clinical isolates of HIV-1 in cell culture. Against HIV-2, the EC_{50} ranges from 0.007 to 1.5 $\mu\text{mol l}^{-1}$. The cellular enzymes involved in the phosphorylation of emtricitabine are similar to that of lamivudine. The active triphosphate competitively inhibits reverse transcriptase by being incorporated into the viral genome, and causing termination in DNA chain elongation.

The bioavailability of the capsules and oral solution are 93 and 75%, respectively. Emtricitabine is rapidly and extensively absorbed following oral administration with peak plasma concentrations occurring at 1–2 h post dose.

The mean plasma elimination half-life of emtricitabine after a single dose is about 8–10 h in HIV-infected patients. However, after multiple doses of the drug at a dose of 200 mg daily, the intracellular half-life is approximately 39 h. The high intracellular levels of emtricitabine triphosphate achieved are associated with better suppression of plasma HIV RNA. Emtricitabine is not an inhibitor of human CYP450 enzymes. Emtricitabine is eliminated by a combination of glomerular filtration and active tubular secretion.

Clinical indications

Emtricitabine is used with other anti-HIV agents. It is administered orally at a once-daily 200 mg capsule. Emtricitabine is a component of Truvada (a fixed-dose combination of emtricitabine and tenofovir disoproxil fumarate), and Atripla (a fixed-dose combination of efavirenz, emtricitabine, and tenofovir disoproxil fumarate).

Adverse effects

The most common adverse events are headache, diarrhea, nausea, and rash, which are generally of mild to moderate severity. Approximately 1% of patients discontinued participation in clinical trials due to these events.

Tenofovir disoproxil fumarate

Chemistry, mechanism of action, and antiviral activity

Tenofovir disoproxil fumarate is (a prodrug of tenofovir), 9-[(*R*)-2-[[bis[(isopropoxycarbonyl)oxy]methoxy]phosphinyl]methoxy]propyl]adenine fumarate (1:1), converted to tenofovir, an acyclic nucleoside phosphonate (nucleotide) analogue of adenosine 5'-monophosphate. Tenofovir disoproxil fumarate requires initial diester hydrolysis for conversion to tenofovir and subsequent phosphorylations by cellular enzymes to form tenofovir triphosphate. Tenofovir triphosphate inhibits the activity of HIV-1 reverse transcriptase by competing with the natural substrate deoxyadenosine 5'-triphosphate and, after incorporation into DNA, by DNA chain termination. Tenofovir triphosphate is a weak inhibitor of mammalian DNA polymerases α , β , and mitochondrial DNA polymerase γ . Tenofovir has antiviral activity *in vitro* against HIV-1 with IC_{50} values ranging from 0.5 to 2.2 $\mu\text{mol l}^{-1}$. The IC_{50} values of tenofovir against HIV-2 range from 1.6 to 4.9 $\mu\text{mol l}^{-1}$.

The oral bioavailability of tenofovir in fasting patients is approximately 25%. Following oral administration of a single dose of 300 mg to HIV-1 infected patients, maximum serum concentrations are achieved in 1.0 ± 0.4 h. C_{max} and AUC values are 296 ± 90 ng ml^{-1} and 2287 ± 685 ng h ml^{-1} , respectively. The oral bioavailability increases when tenofovir is administered after a high-fat meal (40–50% fat). *In vitro* studies indicate that neither tenofovir disoproxil nor tenofovir are substrates of CYP450 enzymes. Tenofovir is primarily excreted by the kidneys by a combination of glomerular filtration and active tubular secretion. The pharmacokinetics of tenofovir is altered in patients with renal impairment.

Clinical indications

Tenofovir is used in combination with other anti-HIV agents for the treatment of HIV-1 infection. It is administered orally once daily, 300 mg tablet.

Adverse effects

The most common adverse reactions seen in a double-blind comparative controlled study were mild to moderate gastrointestinal events and dizziness. However, the following adverse events have been identified during post-approval use of tenofovir; allergic reaction, hypophosphatemia, lactic acidosis, dyspnea, abdominal pain, increased amylase, pancreatitis, increased liver enzymes, hepatitis, renal insufficiency, renal failure, fanconi syndrome, proximal tubulopathy, proteinuria, increased creatinine, acute tubular necrosis, and nephrogenic diabetes insipidus.

Resistance to nucleoside/nucleotide analogue

Nucleoside analogue-associated mutations (NAMs) develop by at least three pathways: (1) accumulation of zidovudine or thymidine analogue resistance mutations (TAMs), (e.g., 41 L, 67 N, 70R, 210 W, 215Y/F, and 219Q/E); (2) selection of the key 151 M mutation, followed by the mutations 62 V, 75I, 77 L, and 116Y, referred to as the 151 complex; and (3) the 69 insertion complex, consisting of a mutation at codon 69 (typically Ser), followed by an insertion of two or more amino acids (e.g., Ser-Ser, Ser-Arg, or Ser-Gly) and generally accompanied by other NAMs. In clinical isolates, two TAM pathways have been observed: 41 L, 210 W, 215Y/F and 67 N, 70R, 219Q/E/N/R; of these, the 41–210–215 combination is the most prevalent. The cytidine analogue select for the M184V mutation (lamivudine, and emtricitabine), while the K65R is seen with tenofovir selection pressure.

Resistance patterns with earlier nucleoside analogue combinations (zidovudine or stavudine with lamivudine)

The resistance profiles seen with earlier nucleoside analogue combinations are well characterized. With thymidine-based NRTIs (lamivudine/zidovudine or stavudine/lamivudine), the M184V mutation emerges rapidly, whereas TAMs are slower to arise. The use of emtricitabine in place of lamivudine would presumably yield similar results, although clinical data are limited. The M184V mutation has been shown to increase zidovudine susceptibility in the absence or presence of zidovudine resistance mutations and without regard to which TAM combination is present. The M184V mutation may increase sensitivity to tenofovir.

The most commonly observed mutations with zidovudine/didanosine or stavudine/didanosine are TAMs. TAMs and multi-nucleoside resistance (MNR) mutations (Q151M, T69 insert) are more prevalent in didanosine-containing regimens than in lamivudine-containing regimens.

Resistance patterns with new nucleoside/nucleotide analogue combinations

With abacavir/lamivudine as backbone, the most common mutation selected for is M184V/I followed by the L74V mutation at treatment failure. The K65R is the major mutation selected *in vitro* by tenofovir alone or in combination with abacavir or lamivudine while abacavir appears to favor L74V and K65R.

In triple-nucleoside/nucleotide regimens (tenofovir/lamivudine/didanosine or tenofovir/lamivudine/abacavir) that lack a thymidine analogue, early treatment failure has been associated with a high frequency of M184V. In addition, 50% of the patients with M184V also harbor the K65R.

Non-nucleoside reverse transcriptase inhibitors

Nevirapine

Chemistry, mechanism of action, and antiviral activity

Nevirapine (11-cyclopropyl-5,11-dihydro-4-methyl-6H-dipyrido[3,2-b:2',3'-e]; [1,4]diazepin-6-one) is a reverse transcriptase inhibitor of HIV-1. However, its mechanism of action is different from nucleoside analogue. It binds to a hydrophobic pocket adjacent to the active site of the reverse transcriptase and causes conformational changes that affect replication. Nevirapine has a bioavailability of approximately 65%. Peak serum concentration of $3.4 \mu\text{g ml}^{-1}$ is achieved approximately 4 h after a 400 mg oral dose. Nevirapine is metabolized by liver microsomes to hydroxymethyl-nevirapine.

Clinical indications

Nevirapine is used in combination with other anti-HIV agents. It is administered orally at 200 mg day^{-1} for the first 14 days (one 200 mg tablet per day), then 400 mg day^{-1} (two daily 200 mg tablets). Single-dose nevirapine is used widely in resource-limited settings to prevent mother-to-child transmission of HIV infection.

Adverse effects

The most common adverse effects include the development of a nonpruritic rash in as many as 50% of patients who received 400 mg day^{-1} . In addition, fever, myalgias, headache, nausea, vomiting, fatigue, and diarrhea have also been associated with administration of drug.

Resistance

Changes in two sets of amino acid residues (100–110 and 180–190) in the reverse transcriptase gene confer resistance to nevirapine. Nevirapine monotherapy is associated with resistance most frequently appearing at codon 181.

Delavirdine

Delavirdine

Chemistry, mechanism of action, and antiviral activity

Delavirdine (1-[5-methanesulfonamido-1*H*-indol-2-yl-carbonyl]-4-[3-(1-methylethylamino) pyridinyl] piperazine) is a second-generation bis (heteroaryl) piperazine licensed for the treatment of HIV infection. Its mechanism of action is similar to that of nevirapine. It is absorbed rapidly when given orally with bioavailability of >60%. Delavirdine is metabolized by the liver with an elimination $T_{1/2}$ of approximately 1.4 h. It has an inhibitory concentration against HIV-1 of approximately $0.25 \mu\text{mol l}^{-1}$. Inhibitory concentrations for human DNA polymerases are significantly higher.

Clinical indications

Delavirdine is used in combination with other anti-HIV agents. It is administered at 1200 mg day^{-1} (two 200 mg tablets three times a day).

Adverse effects

Delavirdine administration is associated with a maculopapular rash. Other side effects are less common.

Resistance

Delavirdine resistance can be generated rapidly both *in vitro* and *in vivo* with the codon change identified at 236, resulting in an increase and susceptibility to $>60 \mu\text{mol l}^{-1}$. Delavirdine resistance can be conferred by mutations at codons 181 and 188, as seen with other non-nucleoside analogue.

Efavirenz

Efavirenz

Chemistry, mechanism of action, and antiviral activity

Efavirenz [(*S*)-6-chloro-4-(cyclopropylethynyl)-1,4-dihydro-4 (trifluoromethyl)-2*H*-3,1-benzoxazin-2-one] is a non-NRTI that can be administered once daily. Activity is mediated predominately by noncompetitive inhibition of HIV-1 reverse transcriptase. HIV-2 reverse transcriptase, and human cellular DNA polymerases α , β , γ , and δ are not inhibited by efavirenz. The 90–95% inhibitory concentration of efavirenz is approximately $1.7\text{--}25 \text{ nmol l}^{-1}$.

Clinical indications

Efavirenz is used in combination with other antiretroviral agents for the treatment of HIV-1 infection. Combination therapy has resulted in a 150-fold or greater decrease in HIV-1 RNA levels.

Adverse effects

The most common adverse events are skin rash (25%), which is associated with blistering, moist desquamation, or ulceration (1%). In addition, delusions and inappropriate behavior have been reported in 1 or 2 patients per 1000.

Resistance

Resistance to efavirenz is caused by mutation in the reverse transcriptase gene as with other non-nucleoside analogue, and appears rapidly.

Etravirine

Chemistry, mechanism of action, and antiviral activity

Etravirine (4-[[6-amino-5-bromo-2-[(4-cyanophenyl) amino]-4-pyrimidinyl]oxy]-3,5-dimethylbenzonitrile) is a non-NRTI with activity against HIV-1 and HIV-2. Etravirine has activity against NNRTI-resistant viruses in the nanomolar range (Andries et al., 2004). Activity is mediated predominately by noncompetitive inhibition of HIV-1 reverse transcriptase. Etravirine does not inhibit human DNA polymerases α , β , γ , and δ .

Following oral administration, etravirine was absorbed with a $T_{\max}$ of about 2.5–4 h. The absolute bioavailability of etravirine is unknown. Administration of etravirine during fasting conditions decreases the AUC by about 50%. Etravirine is bound to plasma proteins, predominantly to albumin (99.6%). However, its antiviral activity was not affected in the presence of 50% human serum (Andries et al., 2004). Etravirine is metabolized by the liver with an elimination $T_{1/2}$ of approximately 41 (± 20) h. Etravirine is a substrate of cytochrome P450 isoenzymes. Drug that induce or inhibit cytochrome P450 isoenzymes may alter the therapeutic effect or side effects of etravirine.

Clinical indications

Efavirenz is used in combination with other antiretroviral agents for the treatment of HIV-1 infection. The recommended dose is 200 mg twice daily following a meal.

Adverse effects

The most common adverse events of moderate to severe intensity (at least 2%) are skin rash and peripheral neuropathy (Lazzarin et al., 2007).

Resistance

Resistance to etravirine is caused by mutation in the reverse transcriptase gene as with other NNRTIs. However, unlike other NNRTIs concurrent presence of three or more of these mutations are required to substantially reduce susceptibility to etravirine (Lazzarin et al., 2007).

Rilpivirine

Chemistry, mechanism of action, and antiviral activity

Rilpivirine (4-[[4-[[4-[(E)-2-cyanoethenyl]-2,6-dimethylphenyl]amino]-2-pyrimidinyl]amino]benzonitrile monohydrochloride) is diarylpyrimidine NNRTI of HIV-1) and inhibits HIV-1 replication by non-competitive inhibition of HIV-1 RT. Rilpivirine does not inhibit human cellular DNA polymerases α , β , γ , and δ .

After oral administration, the maximum plasma concentration of rilpivirine is generally achieved within 4–5 h; the absolute bioavailability is unknown. Rilpivirine is approximately 99.7% bound to plasma proteins *in vitro*, primarily to albumin. Rilpivirine

is primarily metabolized by cytochrome P450 (CYP3A), and drugs that induce or inhibit CYP3A may thus affect the clearance of rilpivirine. The elimination $T_{1/2}$ of rilpivirine is approximately 50 h.

Clinical indications

Rilpivirine is used in combination with other antiretroviral agents for the treatment of HIV-1 infection. The recommended dose is 25 mg orally once a day with a meal. Rilpivirine is as effective as efavirenz in HIV treatment-naïve patients. However, development of resistance and virologic failure occur more frequently with rilpivirine than with efavirenz (Cohen et al., 2011; Molina et al., 2011).

Adverse effects

Adverse effects of rilpivirine include depression, insomnia, headache, and rash. Fewer patients discontinued rilpivirine containing therapy due to adverse effects than with efavirenz containing therapy (3% vs. 8%).

Resistance

Resistance to rilpivirine is caused by mutation in the reverse transcriptase gene as with other NNRTI. Cross-resistance to efavirenz, etravirine and/or nevirapine is likely after virologic failure and development of rilpivirine resistance.

Integrase Inhibitors

Raltegravir

Chemistry, mechanism of action, and antiviral activity

Raltegravir, a structural analogue of a class of compounds with a distinct diketo acid moiety, is a novel HIV-1 integrase inhibitor with potent *in vitro* activity against HIV-1 (IC_{95} of 33 nmol l^{-1}) in the presence of 50% human serum. It is active against a wide range of wild-type and multidrug-resistant HIV-1 clinical isolates and has potent activity against viruses that use CCR5 and/or CXCR4 coreceptors for entry.

Raltegravir is absorbed rapidly, with median T_{max} values in the fasting state of about 1 h; plasma concentrations decrease from C_{max} in a biphasic manner, with a half-life of approximately 1 h for the initial (α) phase and an apparent half-life of approximately 7–12 h for the terminal (β) phase. The pharmacokinetic data for raltegravir are supportive of twice daily administration. It is metabolized by hepatic glucuronidation and has no effect on CYP3A4. Approximately 7–14% of the raltegravir dose is excreted unchanged in urine.

Clinical indications

Raltegravir received priority approval from the FDA (October 2007) for treatment of HIV-1 infection in combination with other antiretroviral agents in treatment-experienced patients with evidence of HIV-1 replication despite ongoing antiretroviral therapy. The dosage of raltegravir is 400 mg administered orally, twice daily with or without food.

Adverse effects

Side effects (mostly mild to moderate) were seen with similar frequency in the raltegravir and placebo arms; the rate of serious adverse events was less than 3% across arms. No lipid abnormalities have been reported so far with raltegravir.

Resistance

Several mutations have been identified in patients failing raltegravir containing regimen including S230R, G163R, N155H, Q148K/R/H, Y143R/C/H, G140S/A, T97A, and L74M (da Silva et al., 2010).

Elvitegravir

Chemistry, mechanism of action, and antiviral activity

Elvitegravir is a first generation HIV-1 integrase inhibitor with potent *in vitro* activity against HIV-1. It is active against a wide range of wild-type and multidrug-resistant HIV-1 clinical isolates and has potent activity against viruses.

Elvitegravir is rapidly absorbed and achieves the maximum concentration in 2–4 h. As elvitegravir is metabolized by CYP3A4, its half-life is significantly increased by co-administration with a pharmaco-enhancer like ritonavir, which inhibits the CYP3A4 metabolic pathway. Twice daily 800 mg dosing of elvitegravir alone to steady-state conditions achieved an AUC_{0-24h} of 3570 $\mu g \cdot h \cdot ml^{-1}$ (37 %CV) and a C_{24h} of 48.0 $\mu g \cdot ml^{-1}$ (33 %CV). However, when 50 mg of elvitegravir was boosted with

100 mg of ritonavir the AUC_{0-24h} and C_{24h} increased to $8840 \mu g \cdot h \cdot ml^{-1}$ (26 %CV) and a C_{24h} of $135.0 \mu g \cdot ml^{-1}$ (37 %CV), respectively (Mathias et al., 2009).

Clinical indications

Elvitegravir was approved by the FDA in August 2012 as part of a fixed-dose daily tablet containing tenofovir, emtricitabine, and the cytochrome P450 isoenzyme 3A (CYP3A) inhibitor cobicistat for treatment of HIV-1 infection (Sax et al., 2012).

Adverse effects

Adverse effects of elvitegravir appear to be few but may include diarrhea and rash. Laboratory abnormalities include elevations in hepatic transaminases.

Resistance

Resistance to elvitegravir is associated with the selection of 1 or more resistance mutations. *In vitro* and *in vivo* studies show the emergence of a number of integrase mutations, including T66I, E92Q, Q148R, and N155H.

Dolutegravir

Chemistry, mechanism of action, and antiviral activity

Dolutegravir (4R,12aS)-9-[[[(2,4-difluorophenyl)methyl]carbamoyl]-4-methyl-6,8-dioxo-3,4,6,8,12,12a-hexahydro-2H-pyrido[1',2':4,5]pyrazino[2,1-b][1,3]oxazin-7-olate) is a second generation HIV-1 integrase inhibitor with subnanomolar EC_{50} antiviral activity *in vitro* (Kobayashi et al., 2011). 50 mg daily monotherapy of dolutegravir for 10 days in HIV-1 infected adults resulted in a 2.48 mean $\log_{10}$ reduction in HIV-1 RNA (Min et al., 2011).

Dolutegravir is absorbed rapidly, with a dose-dependent kinetics and low apparent clearance with oral terminal $T_{1/2}$ of about 15 h; supporting once daily dosing without the need for a boosting agent (Min et al., 2010). 50 mg dosing of dolutegravir to steady-state conditions achieved a geometric mean C_{max} of $3.34 \mu g \cdot ml^{-1}$ (16 %CV), an AUC_{0-24h} of $43.4 \mu g \cdot h \cdot ml^{-1}$ (20 %CV), a $T_{1/2}$ of 12.0 h (22 %CV) and a C_{24h} of $0.83 \mu g \cdot ml^{-1}$ (26 %CV). It is metabolized primarily via UGT1A1 with minor contribution by CYP3A and is a substrate for P-glycoprotein. It is not an inducer or inhibitor of CYP3A (Min et al., 2010). Approximately 64% and 32% of the dolutegravir dose is recovered unchanged in feces and urine, respectively (Castellino et al., 2013).

Clinical indications

Dolutegravir received priority approval from the FDA in August 2013 for treatment of HIV-1 infection in combination with other antiretroviral agents in adults and children aged 12 years and older and weighing at least 40 kg. The dosage of dolutegravir is 50 mg administered orally once daily with or without food. The dosage of dolutegravir is 50 mg twice daily when coadministered with the following potent UGT1A/CYP3A inducers: efavirenz, fosamprenavir/ritonavir, tipranavir/ritonavir, or rifampin.

Adverse effects

Dolutegravir was generally well tolerated effects during clinical trials. Adverse effects of at least moderate intensity (grade 2–4) occurring in $\geq 2\%$ of treatment-naïve participants on dolutegravir were insomnia (3%) and headache (2%) (Walmsley et al., 2013). In some treatment-naïve participants, small mean elevations in serum creatinine ranging from 0.1 to 0.2 mg dl^{-1} were observed.

Resistance

Dolutegravir has a higher barrier to resistance than raltegravir and elvitegravir. *In vitro* as well as clinical data indicate that HIV-1 with primary mutations at codon 155 or 143, and the T66I and E92Q mutants remain susceptible to dolutegravir, whereas mutations at codon 148 in the presence of other secondary mutations (L74I/M, E138A/D/K/T, G140A/S, Y143H/R, E157Q, G163E/K/Q/R/S, or G193E/R) can lead to decreased dolutegravir efficacy (Hare et al., 2011).

Protease Inhibitors

Protease inhibitors are used in combination with other anti-HIV agents for treatment of HIV infection. They are a potent component of HAART regimens. Protease inhibitors are used in combination with ritonavir as the boosting protease inhibitor. The concept of boosting involves pharmacokinetic drug interactions; currently available protease inhibitors are metabolized in the liver by the cytochrome P450 3A4 (CYP3A4) enzyme system. Ritonavir is the most powerful enzyme inhibitor in the protease inhibitor class. The combination with ritonavir allows the boosted protease inhibitor to maintain

prolonged blood levels. This allows for decreased dosage, and reduces a three times a day schedule to a twice daily or even a once daily regimen.

Long-term HAART containing protease inhibitors has been most strongly associated with syndromes characterized by dyslipidemia, peripheral lipodystrophy, and insulin resistance.

Saquinavir

Chemistry, mechanism of action, and antiviral activity

Saquinavir (*cis*-*N*-tert-butyl-decahydro-2[2(*R*)-hydroxy-4-phenyl-3-(*S*)-([*N*-(2-quinolylcarbonyl)-Lasparginyl] amino butyl)-4a*S*, 8a*S*]-isoquinoline-3[*S*]-carboxamide methanesulfonate) is a hydroxyethylamine-derived peptidomimetic HIV protease inhibitor. Saquinavir inhibits HIV-1 and HIV-2 at concentrations of 10 nmol l⁻¹ and is synergistic with other nucleoside analogue as well as selected protease inhibitors.

Oral bioavailability is approximately 30% with extensive hepatic metabolism. Peak plasma concentrations of 35 mg μl⁻¹ are obtained following a 600 mg dose.

The clinical efficacy of saquinavir is limited by poor oral bioavailability but improved formulation (soft-gel capsule) enhances efficacy. Saquinavir is boosted with 100 mg twice a day of zidovudine to improve its bioavailability and efficacy even against saquinavir-resistant HIV strains.

Adverse effects

Adverse effects are minimal with no dose-limiting toxicities. Abdominal discomfort, including diarrhea and nausea, has been reported infrequently.

Resistance

Mutations at codon sites 90 and 48 of the protease gene result in approximately a 30-fold decrease in susceptibility to saquinavir.

Indinavir

Chemistry, mechanism of action, and antiviral activity

Indinavir {*N*-[2(*R*)-hydroxy-1(*S*)-indanyl]-5-[2(*S*)-(1,1-dimethylethylaminocarbonyl)-4-(pyridin-3-yl) methylpiperazin-1-yl]-4[*S*]-hydroxy-2[*R*]-phenylmethyl pentanamide} is a peptidomimetic HIV-1 and HIV-2 protease inhibitor. At concentrations of 100 nmol l⁻¹, indinavir inhibits 90% of HIV isolates. Indinavir is rapidly absorbed with a bioavailability of 60% and achieves peak plasma concentrations of 12 μmol l⁻¹ after a 800 mg oral dose.

Adverse effects

Although indinavir is well tolerated, commonly encountered adverse effects include indirect hyperbilirubinemia (10%) and nephrolithiasis (5%).

Resistance

Indinavir resistance develops rapidly with monotherapy and occurs at multiple sites. The extent of resistance is directly related to the number of codon changes in the HIV protease gene. Codon 82 is a common mutation in indinavir-resistant HIV isolates.

Ritonavir**Chemistry, mechanism of action, and antiviral activity**

Ritonavir (10-hydroxy-2-methyl-5[1-methylethyl]-1[2-(1-methylethyl)-4-thiazolyl]-3,6,dioxo-8,11-bis[phenylmethyl]-2,4,7,12-tetra azatridecan-13-oic-acid, 5 thiazolylmethylester, [5S-(5R, 8R,10R, 11R)]) is an HIV protease inhibitor with activity *in vitro* against HIV-1 laboratory strains ($0.02\text{--}0.15\ \mu\text{mol l}^{-1}$). It is synergistic when administered with nucleoside analogue. Oral bioavailability is approximately 80%, with peak plasma levels of approximately $1.8\ \mu\text{mol l}^{-1}$ after 400 mg administered every 12 h. The plasma half-life is approximately 3 h.

Adverse effects

Adverse effects include nausea, diarrhea, and headache, but all occur at a low frequency.

Resistance

Ritonavir has cross-resistance to indinavir. Mutations at codon 82 are the most common.

Nelfinavir**Chemistry, mechanism of action, and antiviral activity**

Nelfinavir [3S-(3R, 4aR, 8aR, 22'S, 3'S)]-2-[2''-hydroxy-3'-phenylthiomethyl-4'-aza-5'-ox-o-5'-(2''methyl-3'-hydroxyphenyl)pentyl]-decahydroiso-quinoline-3-N-(tert-butyl-carboxamide methanesulfonic acid salt) is another peptidomimetic HIV protease inhibitor. Inhibitory concentrations of HIV-1 are in the range of $20\text{--}50\ \text{nmol l}^{-1}$. It has anti-HIV-2 activity. Nelfinavir is orally bioavailable at approximately 40%, achieving peak plasma concentrations of 2 or 3 mg following a 800 mg dose every 24 h. The drug is metabolized by hepatic microsomes.

Adverse effects

Nelfinavir is well tolerated with mild gastrointestinal complication reported.

Resistance

Cross-resistance to other protease inhibitors, particularly saquinavir, indinavir, or ritonavir, is not common. The most frequently demonstrated site of mutation is at codon 30.

Amprenavir**Chemistry, mechanism of action, and antiviral activity**

Amprenavir is a hydroxyethylamine sulfonamide peptidomimetic with a structure identified as (3*S*)-tetrahydro-3-furyl *N*-(1*S*,2*R*)-3-(4-amino-*N* isobutylbenzenesulfonamido)-1-benzyl-2-hydroxypropylcarbamate. It is active at a concentration of 10–20 nmol l⁻¹. The oral bioavailability is >70% and peak plasma concentrations of 6.2–10 µg ml⁻¹ are achieved after dosages of 600–1200 mg. The plasma half-life is 7–10 h. CSF concentrations are significant. Amprenavir is metabolized in the liver by the cytochrome P450 3A4 (CYP3A4) enzyme system.

Adverse effects

The most common adverse events are gastrointestinal events (nausea, vomiting, diarrhea, and abdominal pain/discomfort), which are mild to moderate in severity. Also, skin rash can occur in patients on amprenavir.

Resistance

Genotypic analysis of isolates from treatment-naïve patients failing amprenavir-containing regimens showed mutations in the HIV-1 protease gene resulting in amino acid substitutions primarily at positions V32I, M46I/L, I47V, I50V, I54L/M, and I84V, as well as mutations in the p7/p1 and p1/p6 Gag and Gag-Pol polyprotein cleavage sites.

Fosamprenavir**Chemistry, mechanism of action, and antiviral activity**

Fosamprenavir, a prodrug of amprenavir [(3*S*)-tetrahydrofuran-3-yl (1*S*,2*R*)-3-[[[(4-aminophenyl) sulfonyl](isobutyl) amino]-1-benzyl-2-(phosphonoxy) propylcarbamate monocalcium salt], is an inhibitor of human HIV protease. Fosamprenavir is rapidly hydrolyzed to amprenavir by enzymes in the gut epithelium. After administration of a single dose of fosamprenavir to

HIV-1-infected patients, the peak concentration occurs between 1.5 and 4 h (median 2.5 h). Amprenavir is metabolized in the liver by the cytochrome P450 3A4 (CYP3A4) enzyme system. The plasma elimination half-life of amprenavir is approximately 7.7 h.

Adverse effects

Side effects profile is similar to that of amprenavir.

Resistance

Fosamprenavir selects for amprenavir-associated mutations on treatment failure, though, at a much lower incidence.

Lopinavir

Chemistry, mechanism of action, and antiviral activity

Lopinavir [N-(4(S)-(2-(2,6-dimethylphenoxy)-acetylamino)-3(S)-hydroxy-5-phenyl-1(S)-benzylpentyl)-3-methyl-2(S)-(2-oxo(1,3-diazaperhydroinyl)butanamin)] is an inhibitor of the HIV protease, prevents cleavage of the Gag-Pol polyprotein, resulting in the production of immature, noninfectious viral particles. It is coformulated with ritonavir at 4:1 ratio (Kaletra). In the presence of 50% human serum, the mean EC_{50} values of lopinavir against HIV-1 laboratory strains ranges from 65 to 289 nmol l^{-1} (0.04–0.18 $\mu\text{g ml}^{-1}$). It has some activity against HIV-2 strains. Lopinavir peak plasma concentration occurs approximately 4 h after administration. Lopinavir is metabolized by CYP3A, and ritonavir inhibits the metabolism of lopinavir, thereby increasing the plasma levels of lopinavir.

Adverse effects

Most common adverse events are nausea, diarrhea, increased cholesterol and triglycerides, and lipodystrophy.

Resistance

Virologic response to lopinavir/ritonavir has been shown to be affected by the presence of three or more of the following amino acid substitutions in protease at baseline: L10F/I/R/V, K20M/N/R, L24I, L33F, M36I, I47V, G48V, I54L/T/V, V82A/C/F/S/T, and I84V.

Atazanavir

Chemistry, mechanism of action, and antiviral activity

Atazanavir [(3S,8S,9S,12S)-3,12-Bis(1,1-dimethylethyl)-8-hydroxy-4,11-dioxo-9 (phenylmethyl)-6-[[4-(2-pyridinyl)phenyl]methyl]-2,5,6,10,13-pentaazatetradecanedioic acid dimethyl ester, sulfate (1:1)] is an azapeptide inhibitor of HIV-1 protease.

Atazanavir exhibits anti-HIV-1 activity with an EC_{50} in the absence of human serum of 2–5 nmol l^{-1} against a variety of laboratory and clinical HIV-1 isolates *in vitro*.

Atazanavir is rapidly absorbed with a T_{max} of approximately 2.5 h. Atazanavir is metabolized in the liver by the cytochrome P450 3A4 (CYP3A4) enzyme system. The mean elimination half-life of atazanavir in healthy volunteers and HIV-infected adult patients is approximately 7 h.

Adverse effects

The most common adverse event in patients is the asymptomatic elevations in indirect (unconjugated) bilirubin related to inhibition of UDP-glucuronosyl transferase (UGT). The hyperbilirubinemia is reversible upon discontinuation of atazanavir. Atazanavir may cause abnormal electrocardiogram findings, increased serum glucose, and lipodystrophy in some patients.

Resistance

HIV-1 isolates with a decreased susceptibility to atazanavir have been selected *in vitro* and obtained from patients treated with atazanavir or atazanavir/ritonavir. The mutations associated with resistance to atazanavir are I50L, N88S, I84V, A71V, and M46I. Atazanavir-resistant clinical isolates from treatment-naïve harbored the I50L mutation (after an average of 50 weeks of atazanavir therapy), often, in combination with an A71V mutation. However, the viral isolates with the I50L mutation are phenotypically resistant to atazanavir but show *in vitro* susceptibility to other protease inhibitors (amprenavir, indinavir, lopinavir, nelfinavir, ritonavir, and saquinavir).

Tipranavir

Chemistry, mechanism of action, and antiviral activity

Tipranavir [2-Pyridinesulfonamide, N-[3-[(1R)-1-[(6R)-5,6-dihydro-4-hydroxy-2-oxo-6-(2-phenylethyl)-6-propyl-2H-pyran-3-yl]propyl]phenyl]-5-(trifluoromethyl)] is a nonpeptidic HIV protease inhibitor belonging to the class of 4-hydroxy-5,6-dihydro-2-pyrone sulfonamides. Tipranavir inhibits the replication of laboratory strains of HIV-1 and clinical isolates *in vitro*, with EC_{50} ranging from 0.03 to 0.07 $\mu\text{mol l}^{-1}$ (18–42 ng ml^{-1}).

The effective mean elimination half-life of tipranavir/ritonavir in healthy volunteers and HIV-infected adult patients is approximately 4.8 and 6.0 h, respectively, at steady state following a dose of 500/200 mg twice daily with a light meal. Tipranavir is predominantly metabolized by the CYP 3A4 enzyme system.

Tipranavir, coadministered with 200 mg of ritonavir, is used in combination with other anti-HIV agents for the treatment of HIV-1 infected adult who are highly treatment-experienced with evidence of viral replication, or have HIV-1 strains resistant to multiple protease inhibitors. Response rates are reduced if five or more protease inhibitor-associated mutations are present at baseline and patients are not given concomitant enfuvirtide with tipranavir/ritonavir.

Adverse effects

Adverse events include rash, increased cholesterol, increased triglycerides, lipodystrophy, and hepatitis. There have been reports of both fatal and nonfatal intracranial hemorrhage with the use of tipranavir/ritonavir. Tipranavir/ritonavir should be used with caution in patients who may be at risk of increased bleeding from trauma, surgery or other medical conditions, or who are receiving medications known to increase the risk of bleeding such as antiplatelet agents or anticoagulants.

Resistance

HIV-1 isolates that were 87-fold resistant to tipranavir were selected *in vitro* by 9 months and contained 10 protease mutations that developed in the following order: L33F, I84V, K45I, I13V, V32I, V82L, M36I, A71V, L10F, and I54V/T. In clinical trials

tipranavir had less than fourfold decreased susceptibility against 90% of HIV-1 isolates resistant to amprenavir, atazanavir, indinavir, lopinavir, nelfinavir, ritonavir, or saquinavir. Tipranavir-resistant viruses selected for *in vitro* have decreased susceptibility to the protease inhibitors amprenavir, atazanavir, indinavir, lopinavir, nelfinavir, and ritonavir but remain sensitive to saquinavir.

Darunavir

Chemistry, mechanism of action, and antiviral activity

Darunavir, in the form of darunavir ethanolate, has the following chemical name: [(1*S*,2*R*)-3-[[[(4-aminophenyl)sulfonyl]-(2-methylpropyl)amino]-2-hydroxy-1-(phenylmethyl) propyl]-carbamic acid (3*R*,3*aS*,6*aR*)-hexahydrofuro[2,3-*b*]furan-3-yl ester monoethanolate. It is an inhibitor of the HIV protease. Darunavir exhibits activity against laboratory strains and clinical isolates of HIV-1 and laboratory strains of HIV-2 with median EC₅₀ values ranging from 1.2 to 8.5 nmol l⁻¹ (0.7–5.0 ng ml⁻¹). Darunavir, coadministered with 100 mg ritonavir twice daily, was absorbed following oral administration with a *T*_{max} of approximately 2.5–4 h. The absolute oral bioavailability of a single 600 mg dose of darunavir alone and after coadministration with 100 mg ritonavir twice daily was 37 and 82%, respectively. Darunavir is primarily metabolized by CYP3A. Ritonavir inhibits CYP3A, thereby increasing the plasma concentrations of darunavir when given in combination.

Darunavir, coadministered with 100 mg ritonavir, and with other anti-HIV agents, is indicated for the treatment of HIV infection in antiretroviral treatment-experienced adult patients, such as those with HIV-1 strains resistant to more than one protease inhibitor.

Adverse effects

The most common treatment-emergent adverse events (>10%) reported in the *de novo* subjects, regardless of causality or frequency, were diarrhea, nausea, headache, and nasopharyngitis. Other side effects are increased triglycerides, increased cholesterol, lipodystrophy, increased glucose, and increased liver enzyme levels.

Resistance

Darunavir-resistant virus derived in cell culture from wild-type HIV had 6- to 21-fold decreased susceptibility to darunavir and harbored three to six of the following amino acid substitutions S37N/D, R41E/S/T, K55Q, K70E, A71T, T74S, V77I, or I85V in the protease. In phase IIb trial, the amino acid substitution V32I developed on darunavir/ritonavir (600/100 mg twice a day) in greater than 30% of virologic failure isolates and substitutions at amino acid position I54 developed in greater than 20% of virologic failure isolates. Other substitutions that developed in 10–20% of darunavir/ritonavir virologic failure isolates occurred at amino acid positions I15, L33, I47, G73, and L89.

Future Prospects in HIV Therapeutics

The simplification of HAART regimens has been a high priority for many years. As the number of effective drugs increases, so does the number of possible effective regimens. The trend toward fixed-dose combinations and once-daily dosage forms of many antiretroviral drugs has provided welcome relief to patients. The following multi-class fixed dose combination agents have been approved by the FDA: Atripla (efavirenz, emtricitabine and tenofovir); Complera (emtricitabine, rilpivirine, and tenofovir); and Stribild (elvitegravir, cobicistat, emtricitabine, and tenofovir). Not only is their medication burden simplified, but as a consequence of improved adherence to therapy, they should experience better control of HIV and thus reduced morbidity.

New drug discovery strategies attempt at circumventing the current drug resistant problem by focusing on either novel targets or new compounds capable of suppressing HIV strains that are resistant to current inhibitors. There are several nucleoside analogues in preclinical and clinical studies. Notably are the novel 4'-substituted thymidine analogues with potent antiviral activity and less cytotoxic (Yang et al., 2006). An example is the recently discovered 2',3'-didehydro-3'-deoxy-4'-ethynylthymidine, structurally related to stavudine, is a more potent inhibitor of HIV-1 replication and is much less inhibitory to mitochondrial DNA synthesis and cell growth in cell cultures than its progenitor stavudine. The triphosphate metabolite accumulates in cells much longer than stavudine, and exerts persistent antiviral activity even after removal of drug from culture (Paintsil et al., 2007). It also has a unique resistance profile when compared to other thymidine analogues and maintains activity against multidrug resistant HIV strains. There is increasing number of compounds discovered as anti-HIV agents targeted at virtually any step in the replicative cycle of the virus and novel targets in development.

Summary

It is anticipated that new and effective treatments for viral infections will be available with the advent of modern and improved technology, based on molecular biology, combinatorial chemistry, and computer-aided design of compounds with greater specificity targeting on viral life cycle.

Glossary

crcB The *crcB* RNA motif is now called the fluoride riboswitch. A *crcB* motif from *Pseudomonas syringae* was shown to be capable of selectively sensing the very small and highly charged fluoride ion.

Chemolithoautotroph Organism that uses anorganic compounds as electron donors and carbon source.

Chemolithoheterotroph Organism that uses anorganic compounds as electron donors, but organic compounds as carbon source.

Chemoorganoheterotroph Organism that uses organic compounds as electron donors and carbon source.

Abbreviations

Co	Cobalt
Fe	Iron
HGT	Horizontal gene transfer
kbp	Kilo (10^3) base pairs
Mn	Manganese
Moco	Molybdenum cofactor
ORF	Open reading frame
ROS	Reactive oxygen species
rRNA	Ribosomal RNA
SRP RNA	Signal recognition particle RNA
tmRNA	Transfer-messenger RNA

Introduction

The bacterial phylum Aquificae comprises the orders *Aquificales* (families *Aquificaceae* and *Hydrogenothermaceae*) and *Desulfurobacteriales* (family *Desulfurobacteriaceae*) (Gupta and Lali, 2013). Members of the Aquificae inhabit terrestrial and marine hydrothermal systems around the planet. For example, genera from all three families can be isolated at deep-sea vents such as the Eastern Lau Spreading Center and Valu-Fa Ridge (ELSC/VFR) in the Southwestern Pacific (Ferrera et al., 2014), where they inhabit hydrothermal, mineral and sulfur-rich deposits that form when the cold oxygenated seawater mixes with the high temperature hydrothermal fluid. Such geochemical habitats are dominated by mesophilic ϵ -proteobacteria, but Aquificae complement these bacterial communities, evidently by thriving in the higher temperature areas (Ferrera et al., 2014). The phylum members *Aquifex aeolicus* and *Aquifex pyrophilus* are the most temperature-resistant bacteria known; they grow up to 95°C, whereas other *Aquificales* have upper growth temperature limits of $\sim 80^\circ\text{C}$. The known Aquificae are Gram-negative, non-sporulating and motile bacteria that grow at slightly acidic ($\sim \text{pH } 5$) to neutral pH and which are adapted to the salinity of their habitats (Guiral et al., 2012). They are primarily chemolithoautotrophs that utilize anorganic compounds as energy source (electron donor) and obtain carbon by CO_2 fixation using the reductive tricarboxylic acid (rTCA) cycle. Electron donors are H_2 (with the exception of some *Hydrogenothermaceae* species), elemental sulfur (S^0) or thiosulfate ($\text{S}_2\text{O}_3^{2-}$); electron acceptors are O_2 in the case of the microaerobic *Aquificaceae* and *Hydrogenothermaceae* (some organisms can also use NO_3^- or S^0), whereas the strictly anaerobic *Desulfurobacteriaceae* only utilize sulfur compounds like S^0 or NO_3^- as electron acceptors. Some characteristics of the eleven Aquificae strains with completely assembled genome sequence (or of related strains if the sequenced strains have not been characterized specifically) plus *A. pyrophilus* as a founding member of the phylum (Huber et al., 1992) are summarized in Table 1.

Energy Metabolism – Idiosyncrasies, Commonalities and Differences

Aquifex stands for “water-maker” to indicate H_2 oxidation and terminal electron transfer to O_2 (“Knallgas” reaction). However, some *Sulfurihydrogenibium* strains such as sp. Y03AOP1, *S. yellowstonense* and sp. UZ 3–5 are unable to oxidize H_2

Table 1 Physiological characteristics of members of the phylum Aquificae

^acla: chemolithoautotroph (uses anorganic compounds as electron donors and carbon source); coh: chemoorganoheterotroph (uses organic compounds as electron donors and carbon source); clh: chemolithoheterotroph (uses anorganic compounds as electron donors, but organic compounds as carbon source); ma: microaerob; aa: anaerobic.

^b*Hydrogenivirga caldilitoris* IBSK3 is related to strain *Hydrogenivirga sp.* 128-5-R1-1 (Ferrera *et al.*, 2014) that was subjected to genome sequencing (NCBI, NZ_ABHJ000000000.1); another related strain is *Hydrogenivirga okinawensis* LS12-2 (Nunoura *et al.*, 2008) with the following determined features: a growth temperature range of 65-85°C (optimal 70-75°C); use of S⁰ and S₂O₃²⁻, but not H₂ as electron donors; N₂, S₂O₃²⁻ and SO₄²⁻ as products of energy metabolism; strictly chemolithoautotrophic, microaerobic and anaerobic growth (Nunoura *et al.*, 2008).

^cunable to grow anaerobically with nitrate in the presence of formate, formamide or formaldehyde (Eder and Huber, 2002).

^d*Hydrogenobaculum acidophilum* (optimal pH: 3-4) is related to *Hydrogenobaculum sp.* Y04AAS1 (optimal pH: 4; Ferrera *et al.*, 2007), the strain for which the genome sequence is available. The latter was reported to be unable to reduce nitrate under laboratory conditions (Reysenbach *et al.*, 2009), although genes for nitrate respiration are encoded (Reysenbach *et al.*, 2009; Romano *et al.*, 2013). The optimal growth temperature for strain Y04AAS1 is 58°C (Ferrera *et al.*, 2007). A substantial microdiversity of *Hydrogenobaculum* in Yellowstone National Park samples was observed; ~ half of the genes unique to strain Y04AAS1 relative to *Hydrobacterium sp.* isolates reported in (Romano *et al.*, 2013) were predicted to be acquired by HGT. *Hydrobacterium sp.* can further grow on H₂S as energy source (Romano *et al.*, 2013).

^e*Thermocrinis ruber* isolate OC14/7/2 (DSM No. 23557) was used as authentic type strain instead of the deposited isolate DSM No. 12173 (Huber *et al.*, 1998) which turned out to be non-authentic based on 16S rRNA sequence analysis (Härtig *et al.*, 2014).

^fNo specific strain characterization available; the given data are based on descriptions of the genus *Sulfurihydrogenibium* (Takai *et al.*, 2003; Aguier *et al.*, 2004; Nakagawa *et al.*, 2005; O'Neill *et al.*, 2008).

^goptimally microaerobic conditions, but aerobic conditions (> 10 volume % O₂) tolerated by some species.

^hSome of the products of energy metabolism were inferred from analysis of *Sulfurihydrogenibium subterraneum* (Takai *et al.*, 2003) based on the utilization of the same electron donors/acceptors by *Sulfurihydrogenibium azorensis* Az-Fu1 (Aguier *et al.*, 2004; Nakagawa *et al.*, 2005).

ⁱA novel species, *Desulfurobacterium indicum*, was characterized recently and compared with four other *Desulfurobacterium* species including *D. thermolithotrophum*, which differ in their utilization of terminal electron acceptors (Cao *et al.*, 2017). With H₂ as electron donor, *D. indicum* can utilize S⁰, S₂O₃²⁻ and NO₃⁻ as electron acceptors, but not SO₃²⁻.

(O'Neill et al., 2008; Reysenbach et al., 2009) which is consistent with the failure to identify hydrogenase genes in the corresponding genomes. A commonality of all Aquificae is their capability to fix CO₂ by the rTCA cycle to synthesize acetyl-CoA. While the *Aquificaceae* utilize the presumedly ancestral "B-type" rTCA cycle (cleavage of citrate to oxaloacetate and acetyl-CoA by successive action of two enzymes, citryl-CoA synthetase and citryl-CoA lyase), the "A-type" rTCA cycle (cleavage of citrate to oxaloacetate and acetyl-CoA by the single two-subunit enzyme ATP citrate lyase) is implemented in the other two Aquificae families (Hügler et al., 2007). The *Desulfurobacteriaceae* additionally encode an incomplete reductive acetyl-CoA pathway thought to be the most ancient carbon fixation pathway on earth. Together with their ability to utilize sulfur as electron acceptor and their strictly anaerobic growth, this family was proposed to have retained primordial metabolic components that evolved before the emergence of photosynthesis and the rise of oxygen in the atmosphere (Giovannelli et al., 2017). A common trait of members of the order *Aquificales* is their ability to utilize elemental sulfur or inorganic sulfur compounds as electron donors (Table 1).

Oxidative Stress

Aquificae that grow under microaerobic conditions have to cope with reactive oxygen species (ROS) such as superoxide and peroxide. Three genes encoding superoxide dismutase (one Fe/Mn and two Co/Zn family enzymes) were identified in the *A. aeolicus* genome. However, no catalase gene could be identified, although *Aquifex* cells react with H₂O₂ as inferred from rapid gas production (Huber et al., 1992; Swanson, 2001). Catalase activity, detected in the insoluble fraction of *A. aeolicus* cell lysates, was resistant to acid treatment and could not be extracted by organic solvents from insoluble lysate pellets. Further analysis identified phosphate salts of Fe as a major component of such insoluble fractions. As Fe alone has catalase activity, it has been speculated that *A. aeolicus* may promote the intracellular precipitation of such inorganic Fe-phosphate salts to protect cells against damage by H₂O₂ (Swanson, 2001).

Thermovibrio ammonificans, which grows strictly anaerobic, also encodes proteins that protect against damage by ROS. This includes a catalase/peroxidase, a putative superoxide reductase, a cytochrome c peroxidase and a cytochrome bd complex. The latter was shown to contribute to oxygen tolerance in anaerobic bacteria and to detoxification of nitrous oxide radicals (Giovannelli et al., 2017).

Gluconeogenesis

The Aquificae synthesize pentose and hexose monosaccharides from products of the rTCA cycle by the Embden-Meyerhof-Parnas pathway. The key gluconeogenic enzyme fructose-1,6-bisphosphatase (*fbp*) was identified in *T. ammonificans*, *Desulfobacterium thermolithotrophum*, *Sulfurihydrogenibium* sp. Y03AOP1, *Persephonella marina*, *Hydrogenivirga* 128-5-R-1-1, but not in *Hydrogenobacter thermophilus* and *A. aeolicus*, suggesting a pathway variation in the latter two bacteria (Deckert et al., 1998; Giovannelli et al., 2017). Genes encoding enzymes of the pentose-phosphate pathway and for glycogen synthesis and catabolism were also found in the *A. aeolicus* genome (Deckert et al., 1998).

Motility

All Aquificae are motile, forming one or two (mono- or polytrichous) monopolar flagella. Some members of the phylum, such as *T. ammonificans* and *D. thermolithotrophum*, also encode homologs of the bacterial chemotaxis system (Giovannelli et al., 2017); corresponding genes were not identified in the *A. aeolicus* genome (Swanson, 2001). As the well-characterized bacterial chemotaxis systems respond to the presence of sugars and amino acids, chemolithoautotrophs like *A. aeolicus* may sense other changes, such as concentration of dissolved CO₂, H₂, O₂ or temperature, by other mechanisms (Swanson, 2001).

Sizes and G/C Content of Aquificae Chromosomes

To date (end of 2018), the NCBI genome browser lists 23 Aquificae genome projects. Ten represent complete genome assemblies, all others are in premature assembly states. We also included *Hydrogenivirga* in our comparative genome analyses, as done in a recent study to which we refer here (Lechner et al., 2014; see phylogenetic tree in Fig. 1). The eleven strains are specified in Table 1; if the strain with sequenced genome was not characterized in detail in the literature, we instead describe the features of a closely related strain. In addition, we included the founding strain *A. pyrophilus* with unsequenced genome for comparison of metabolic features (Table 1). Genome sizes are close to the assumed lower limit of genomes in free-living bacteria, ranging from 1.5 (*T. albus*) to ~ 2 Mbp (*P. marina*). The current annotation file of the *Hydrogenivirga* 128-5-R-1-1 genome contains a sequence of 3.04 Mbp, which is roughly double the size as found in other Aquificae. However, the *Hydrogenivirga* sequence file only represents the lowest contig assembly level and there is evidence that the genome assembly is erroneous, likely a blend of two genomes of related bacteria, one from a member of the *Aquificaceae* and the second from a *Hydrogenothermaceae* species. This is inferred from the finding of two 6S

Fig. 1 Maximum likelihood tree of Aquificae based on whole genome alignments. Strains: *Thermocrinis ruber* DSM 23557; *Thermocrinis albus* DSM 14484; *Desulfurobacterium thermolithotrophum* DSM 11699. Reproduced from Lechner, M., Nickel, A.I., Wehner, S., 2014. Genomewide comparison and novel ncRNAs of Aquificales. BMC Genomics 15, 522. doi:10.1186/1471-2164-15-522.

RNA candidates and two different subtype tmRNAs – rather than single loci as in the other Aquificae – as well as an increased number of tRNA genes and CRISPR loci (Lechner et al., 2014). The genome G/C content varies between 32% (*Sulfurihydrogenibium* sp. Y03AOP1) to 52.1% (*T. ammonificans*).

Extrachromosomal Plasmids

Plasmids were isolated and sequenced for *A. aeolicus* (39 kbp, 32 genes), *T. ammonificans* (77 kbp, 97 genes) and *P. marina* (54 kbp, 74 genes). In *A. aeolicus*, on average two plasmid copies were estimated to be present per chromosome. Except for a transposase, ORFs were classified as hypothetical proteins; one plasmid ORF is also present in two identical copies on the chromosome (Deckert et al., 1998). In *T. ammonificans*, the plasmid encodes mostly ORFs with unknown hypothetical functions, except for a putative RNA polymerase sigma factor, a DNA topoisomerase I, a type II secretion protein E and an ArsR-like helix-turn-helix transcription regulator. Furthermore, the plasmid contains highly repeated DNA (Giovannelli et al., 2017). In *P. marina*, apart from mostly hypothetical proteins, the plasmid encodes, among others, an antitoxin, several proteins involved in conjugal plasmid transfer, a site-specific integrase, a type IA DNA topoisomerase, a plasmid replication initiator and segregation proteins.

Protein Genes and mRNA Decoding

The first published Aquificae genome of *A. aeolicus* revealed several idiosyncrasies (Deckert et al., 1998). In the densely packed genome, most genes are part of polycistronic transcription units as in other Bacteria. There are many operons encoding genes of the

same functional context, which is pronounced for ribosomal protein genes, but also seen for many genes involved in energy metabolism, cell envelope biogenesis and processes such as flagella synthesis. Yet, there are also many genes of the same functional context, such as those of the tryptophan and histidine biosynthesis pathways, that are not organized in the same operons as in other Bacteria, but are dispersed in the *A. aeolicus* genome or appear in novel operons. This also pertains to genes for subunits of the same enzyme, for example *glbB* (Aq_1565) and *glbD* (Aq_2064; glutamate synthase), the α and β subunit genes of glycyl and phenylalanine tRNA synthetases (Aq_945/2141 and Aq_953/1730), *ribH/ribC* (Aq_132/1707) encoding the α and β subunits of riboflavin synthase and *nrdA/nrdF* (Aq_94/1505) coding for the α and β chains of ribonucleotide reductase. It has been surmised that the lack of cistronic arrangement of biosynthetic genes may reflect the chemolithoautotrophic life style of Aquificae that is committed to CO₂ fixation. In contrast, chemoorganoheterotrophic microorganisms can metabolically switch between different energy and carbon sources. This is achieved by coordinated up- and down-regulation of transcription units that encode the genes participating in the respective metabolic pathways (Swanson, 2001).

It is also not clear if transcription in the Aquificae may differ from what is known from other bacteria. The RNA polymerase and sigma factors in the genus *Aquifex* have functional properties very similar to those of other bacteria (Klenk et al., 1999; Studholme and Buck, 2000; Studholme et al., 2000), but *A. aeolicus* was reported to lack hairpin structures for transcription termination (Washio et al., 1998). The latter observation might suggest that transcript ends/operon boundaries are less defined, possibly pointing to read-through transcription of longer genomic segments. However, this may not pertain to the entire genome, as potential (though not very stable) hairpin structures were identified at the end of the consecutive *rplAJL* (encoding ribosomal proteins) and *rpoBC* (encoding the β and β' subunits of RNA polymerase) operons in *A. pyrophilus* (Klenk et al., 1999). Many convergently transcribed ORFs in *A. aeolicus* overlap, ranging from simple stop codon overlaps to overlaps of tens of base pairs (Swanson, 2001). In RNA-Seq experiments, high sense and antisense read levels were found in genes encoding validated and putative non-coding RNAs. The same pertains to overlapping 5'-upstream regions of two protein-coding genes located on opposing strands, as well as areas where two 3'-untranslated regions overlap on opposing strands (Lechner et al., 2014). Such RNA reads might be vestiges of extensive transcription of both genome strands, although this remains to be validated.

Whole genome alignments using the software tools Pomago (v. 1.0) and TBA (v. 11.2) revealed that individual genomes have gaps of 10.5%–13% (Pomago) or 8.4%–9.6% (TBA) when aligned to the other ten genomes. The original protein annotations of the genome files were recently extended, predicting for example ~ 6% more proteins with assigned or hypothetical function in *A. aeolicus*. In addition, the 5'- and 3'-ends of ORFs were partially refined. The Shine-Dalgarno sequences in the 11 organisms are quite conserved (5'-GGAGG, always 5'-NGAGN), -10 promoter signatures are more variable though recognizable (A/T-rich). The number of tRNA genes is minimized to 39–46 (*Hydrogenivirga* excluded) compared with > 80 tRNA genes in strains of *Escherichia coli* and *Bacillus subtilis*. With respect to codon usage, the two Arg codons with 5'-A and the Ile AUA codon are preferentially utilized in the Aquificaceae and Hydrogenothermaceae. The preference for AUA correlates with expression of tRNA-Ile lysidine synthetase (TilS) in the Aquificae (a crystal structure of *A. aeolicus* TilS is available). TilS converts the 5'-C residue in the CAU anticodon of specific tRNA-Ile molecules to lysidine (2-lysyl cytidine; abbreviated as L or k²C) to allow decoding of 5'-AUA (Ile) instead of 5'-AUG (Met) codons. Apparently, this anticodon modification enables reliable decoding at high temperatures. Consistent with the reduced number of tRNA genes (39–46) in the Aquificae, multiple copies of tRNA isoacceptor genes are avoided. Almost no tRNAs with 5'-A in the anticodon are encoded and anticodons with 5'-C are reduced in the non-Aquificaceae within the Aquificae. The streamlining of the tRNA repertoire goes along with expression of the tRNA modification enzyme tRNA adenosine deaminase (TadA; crystal structure of the *A. aeolicus* protein available) that converts the anticodon 5'-A residue to inosine in the single tRNA^{Arg} (anticodon 5'-ACG). This allows decoding of codons 5'-CG(U,C,A), while each of the three other tRNA^{Arg} isoacceptors recognize one of the remaining three Arg codons through Watson-Crick base-pairing at all three codon positions. The maintenance of wobble decoding by tRNA^{Arg} (5'-ICG) while decreasing the fraction of 5'-CG(U,C,A) codons in the genome may be a compromise resulting from constraints to downsize the tRNA repertoire and to minimize the number of labile codon:anticodon interactions. The Aquificaceae (except for *Hydrogenobaculum*) and Desulfurobacteriaceae encode selenocysteine-specific tRNAs decoding 5'-UGA codons; those are absent from the Hydrogenothermaceae. The Aquificaceae, but not *Hydrogenivirga* and the other Aquificae, express the lysine tRNA isoacceptor with the anticodon 5'-CUU to stabilize AAG decoding, a feature shared with other thermophilic bacteria (*Thermus thermophilus*, *Thermotoga maritima*). In mesophiles, AAG codons are decoded by isoacceptors harboring the anticodon 5'-UUU.

Non-Coding RNAs (ncRNAs) in the Aquificae

Apart from tRNAs and 1–3 copies of 5S/16S/23S rRNA, bioinformatics identified genes for 6S RNA (except for uncertain candidates in *D. thermolithotrophum* and *T. ammonificans*), a regulator of bacterial RNA polymerase, the signal recognition particle RNA (SRP RNA), and a tmRNA of type A or B; riboswitch candidates were found sporadically in a few species [TPP, Moco, Cobalamin and *crcB* (Lechner et al., 2014)]. Of note, 6S RNA is present in the Aquificaceae and Hydrogenothermaceae, as well as in *Thermodesulfatator indicus* of the Aquificae sister phylum Thermodesulfobacteria, but is absent from the next related phyla (according to 16S rRNA phylogeny), Thermotogae and Deinococcus-Thermus. RNase P RNA is not encoded in the genomes of Aquificaceae, but is present in the two other families. Instead, the Aquificaceae encode a novel type of protein-only RNase P, a PIN_5 domain metallonuclease consisting of a single 23-kDa polypeptide. The genes for the ancient RNA-based enzyme (*rnpB* encoding the RNA and *rnpA* the protein subunit), present in the vast majority of Bacteria, were lost in the Aquificaceae, which represents a novel hallmark feature of

this family. Homologs of *Aquifex* RNase P (HARP) were identified in many Archaea and in a few other bacteria of different phyla; all these Archaea encode an RNA-based RNase P as well. Combined with the assessment that at least 10% of genes in *A. aeolicus* were acquired by horizontal gene transfer (HGT) from Archaea (Aravind et al., 1998), it is very likely that the progenitor of the *Aquificaceae* acquired the HARP gene by HGT from an archaeon (Nickel et al., 2017). In accordance, bootstrap analysis groups all bacterial HARPs with those of archaeal Thermococci, suggesting that bacterial HARPs originate from this class of Euryarchaeota (Nickel et al., 2017).

The *A. aeolicus* genome was analyzed for ncRNA candidates, applying constraints such as a minimum length of 25 nt and no overlap with protein-coding sequences, rRNA or tRNA genes. Since the housekeeping ncRNAs discussed above have a G/C content of 66% in *A. aeolicus*, an elevated G/C content (relative to the 43% average G/C content of the genome) was taken as an additional criterion for ncRNA identity. The analysis identified a candidate list of ~100 ncRNAs in *A. aeolicus* (Lechner et al., 2014), including the housekeeping ncRNAs, such as SRP RNA, tmRNA or 6S RNA. As mentioned before, RNA-Seq data for *A. aeolicus* suggest a substantial level of antisense transcripts for known ncRNAs and novel ncRNA candidates, which could be partly confirmed by Northern blot analyses (Lechner et al., 2014).

Mechanisms of Thermostabilization

Adaptations to growth at high temperatures are evident at the level of cell envelope, genome, RNAs and proteins. The cell membranes of several *Aquificaceae* were found to contain the more stable glycerol-ether phospholipids in addition to acyl glycerides (Jahnke et al., 2001). *A. aeolicus* expresses two reverse gyrases (genes Aq_886 and Aq_1159), which are topoisomerases originally acquired from Archaea by HGT and which introduce positive supercoilings into the DNA. Potential functions include prevention of excess local unwinding of the double helix or protection of DNA against damage (e.g., depurination, strand breakage) at high temperature (Brochier-Armanet and Forterre, 2007; Ogawa et al., 2015). Another adaptation to (hyper)thermophilic conditions is an elevated G/C content of non-coding RNAs (ncRNAs). The ribosomal RNAs of *A. aeolicus* have 65% G/C compared with an average G/C content of ~43% in the bacterium's genomic DNA (Deckert et al., 1998). This G/C-richness, which correlates with enhanced RNA secondary and tertiary structural stability, is also implemented in other ncRNAs of *A. aeolicus*, such as tRNAs, tmRNA or 6S RNA, the thermodynamically most stable 6S RNA known so far (Deckert et al., 1998; Willkomm et al., 2005; Köhler et al., 2015). Increased thermostability of proteins is achieved by multiple adaptations that are not specific for the Aquificae. Of note, alterations relative to mesophilic Bacteria and Archaea differ between moderately and extremely thermophilic organisms, and different protein families have evolved individual strategies to achieve high thermal stability (Szilágyi and Závodszky, 2000). Hyperthermophiles (Archaea and Bacteria such as *A. aeolicus*) have increased proportions of charged amino acids (Lys, Glu) at the expense of polar non-charged amino acids (Asn, Gln, Ser, Thr), indicative of an increase in ion pairs including salt bridges between N- and C-termini (Cambillau and Claverie, 2000; Szilágyi and Závodszky, 2000). Disulfide bonds can also contribute to stabilization, such as in an *Aquifex* serine protease containing eight Cys residues (Choi et al., 1999), ferredoxins (Meyer et al., 2002) or rhodanese (Aq_1599, (Giuliani et al., 2010)). There is a trend to increase the fraction of α -helices and β -strands and to decrease flexible regions (e.g., surface loops) in thermophilic proteins. An example is a thermostable cytochrome *c* equipped with an extra α -helix (Obuchi et al., 2009). C-terminal ends of proteins are frequently folded into the protein core to avoid flexible and accessible regions.

Apart from increases in the number of ion pairs, increases in the number of hydrogen bonds or enhanced core hydrophobicity have been questioned as substantial contributors to extreme thermostability (Szilágyi and Závodszky, 2000). Yet, protein oligomerization is often enhanced. In an archaeal histone dimer, improved intermolecular hydrophobic interactions and additional favorable ion pairs at or near the dimer interface were found to be associated with thermostability, along with the preference for large hydrophobic side chains to reduce cavity sizes and to increase packaging density in the hydrophobic dimer core; in addition, C-terminal protein extension by two Lys residues was proposed to shield the dimer core from solvent exposure (Li et al., 2000). As another example, an *A. aeolicus* rhodanese enzyme (Aq_477) involved in sulfur transfer forms tetramers as a prerequisite for thermostability and enzymatic function. Formation of supercomplexes is another strategy to enhance thermostability. The thermostable sulfide-oxidase and oxygen-reductase supercomplex of *A. aeolicus* was found to be resistant to denaturation/inactivation by up to 8 M urea, 6% Triton X-100 and 1% SDS (Guiral et al., 2012).

Phylogeny

The phylum Aquificae has been defined by 16S rRNA phylogeny, yet its member organisms show phylogenetic, ecological, morphological and metabolic diversity. Several protein-based phylogenies have supported 16S RNA-based phylogenies that place the Aquificae as a deep branching sister phylum of the Thermotogae in the bacterial phylogenetic tree. Other analyses have indicated a closer affiliation with other bacterial groups such as the ϵ -proteobacteria. This is further complicated by bioinformatic evidence that *A. aeolicus* and other Aquificae as well as Thermotogae have acquired many of their protein-coding genes by HGT from Archaea (Aravind et al., 1998; Zhaxybayeva et al., 2009). Two major hypotheses have been formulated to explain the findings of various studies: (a) the Aquificae and the Thermotogae represent the deepest-branching bacterial phyla containing many hyperthermophiles,

with strong affiliations to the ϵ -proteobacteria owing to large-scale gene sharing, and further shaped by acquisition of genes from archaeal thermophiles; (b) the Aquificae are essentially ϵ -proteobacteria or a sister to this group that extensively exchanged genes with other thermophilic lineages such as Thermotogae and Archaea. The large extent of genetic mosaicism, also observed in other Aquificae such as *T. ammonificans* (Giovannelli et al., 2017), led Eveleigh et al. (2013) to conclude that “The evolutionary history of the Aquificae implicates different partner lineages, most notably the Archaea, Thermotogae, δ -proteobacteria, and thermophilic members of Nitrospirae, Clostridia and ϵ -proteobacteria, with different lineages making disproportionate contributions to different molecular subsystems.” Indeed, bioinformatic analysis of *A. aeolicus* proteins from selected functional subsystems (cell wall, flagella, oxidative phosphorylation, ribosomal proteins) revealed different “closest neighboring phyla or classes”, which even differed between the various complexes participating in oxidative phosphorylation (Eveleigh et al., 2013). This mosaic-like origin of genes in a single metabolic pathway also pertains to enzymes involved in the putative reductive acetyl-CoA pathway in *T. ammonificans* (Giovannelli et al., 2017). Eveleigh et al. (2013) favored a scenario according to which most genes with closest relatedness to homologs in thermophiles are derived from HGT, whereas genes related to those in ϵ -proteobacteria are relics of a mesophilic past that preceded colonization of high temperature environments. This takes evidence into account that ϵ -proteobacteria developed diverse strategies to colonize many deep-sea hydrothermal habitats, favored by their high growth rates, rapid adaptations to changing geochemical conditions and metabolic versatility. Finally, it cannot be excluded that the extensive genetic mosaicism in the Aquificae might have erased the traces of their real ancestry.

Glossary

Arbovirus Arthropod-borne virus, a virus that is transmitted between its animal hosts by arthropod vectors.

Serogroup A group of antigenically related viruses.

Viremia Presence of a virus in blood.

Zoonosis An infectious disease episode characterized by the transmission of a pathogen from animals to humans.

Abbreviation

BFV	Barmah Forest virus
CCHFV	Crimean-Congo Hemorrhagic Fever virus
CHIKV	Chikungunya virus
CSF	Cerebrospinal fluid
CT	Computed tomography
DEN	Dengue
DENV	Dengue virus
DF	Dengue fever
DHF	Dengue hemorrhagic fever
DSS	Dengue shock syndrome
EEEV	Equine encephalitis virus
JE	Japanese encephalitis
JEV	Japanese encephalitis virus
KFDV	Kyasanur forest disease virus
MRI	magnetic resonance imaging
MVE	Murray Valley encephalitis virus
NSDV	Nairobi Sheep Disease virus
OHFV	Omsk hemorrhagic fever virus
ONNV	O'nyong-nyong virus
POWV	Powassan virus
RRV	Ross River virus
RVFV	Rift Valley fever virus
SIADH	Syndrome of inappropriate antidiuretic hormone
SINV	Sindbis virus
SLEV	St. Louis encephalitis virus
TBEV	Tick-borne encephalitis virus
VEEV	Venezuelan equine encephalitis virus
WEEV	Western equine encephalitis virus
WNV	West Nile virus
YF	Yellow fever
YFV	Yellow fever virus
ZIKV	Zika virus

[☆]*Change History:* August 2016. David Warrilow changed nomenclature to either formal or informal virus usage as appropriate, updated taxonomic information based on the latest ICTV 2015 report, introduced Zika virus and added a section on this, expanded the arbovirus syndromes to incorporate ZIKV birth defects, made mention of the recent licensed dengue vaccine, added more viruses in the bunyavirus section, added two previously unmentioned arbovirus families infecting humans, overall made multiple minor grammatical changes to improve readability.

This article is an update of A. García-Sastre, T.P. Endy, Arboviruses, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 313–321.

Defining Statement

The arboviruses are a heterogeneous group of viruses transmitted by arthropods. The clinical manifestations of infections in humans by arboviruses range from asymptomatic infections, to a variety of diseases including arthritis, encephalitis, and hemorrhagic fever. The pathogenesis and disease caused by human arboviruses are summarized in this article.

Introduction

The arbovirus group of viruses includes a diverse group of almost exclusively RNA viruses that are transmitted by arthropods to vertebrate human and animal hosts. This group includes positive-strand RNA viruses belonging to the families *Togaviridae* and *Flaviviridae*; negative-strand RNA viruses belonging to the families *Bunyaviridae* and *Orthomyxoviridae*; and a double-stranded RNA virus family *Reoviridae*. Arthropod vectors such as mosquitoes, ticks, sandflies or midges facilitate arbovirus transmission and infection of vertebrate hosts following a blood meal, usually required as a source of protein for egg development. Arboviruses can be maintained in a continued transmission cycle as new uninfected arthropod vectors feed on infected reservoir vertebrate hosts. Virus replication and amplification within the infected arthropod vector usually occurs in the midgut, followed by dissemination and infection of the salivary glands. This allows transmission of the virus into a new vertebrate host when the infected vector bites again. Replication of the virus in the vertebrate host starts at the local site of injection, and viruses are systemically spread via the lymphatic system and the blood to different organs. Subsequent cycles of replication and the presence of virus in the blood (viremia) can result in host viral levels which are sufficient to infect a susceptible vector when it bites, thereby allowing the transmission cycle to continue. However, some arboviruses can be maintained in their arthropod vectors without the need of a vertebrate host through vertical transmission to eggs, allowing survival of the virus even during times when the vertebrate–arthropod cycle is disrupted due to environmental or other ecological factors for prolonged periods of time.

In addition to reservoir vertebrate hosts, there are some species, which although susceptible to arbovirus infection and disease, are unable to sustain viremia levels sufficient for the infection of new vectors. These are dead-end hosts in effect, and represent a spillover of incidental virus transmission from the normal amplification cycle. Some species may participate as reservoir hosts for some arboviruses, but not others. For example, humans are part of the transmission cycle for dengue virus (DENV) and yellow fever virus (YFV), but are dead-end hosts for other flaviviruses such as West Nile virus (WNV) and Japanese encephalitis virus (JEV), whose natural hosts are avian species. Thus, humans infected with DENV or YFV can potentially reach viremia levels required for infection of the mosquito species that transmit these viruses, and therefore are intrinsically important for ongoing transmission of DENV or YFV which can lead to unprecedented outbreaks and widespread epidemics. However, in most instances, humans are considered dead-end hosts in the transmission cycles of many arboviruses.

Although humans can develop severe disease such as encephalitis, as may occur following WNV or JEV infections, generally they do not attain viremia levels necessary to infect mosquito vectors. Transmission of an arbovirus from one human to another can also occur occasionally in the absence of an arthropod intermediate, as is the case if a transplant recipient receives an organ from an infected donor, via blood transfusions or indeed transfer of other bodily fluids as in the case of sexual transmission. Regardless of these factors, the complex interactive transmission cycles of arboviruses require that these viruses adapt to two evolutionary different and distinct hosts: vertebrates and arthropods. This adaptation can be very exquisite, and therefore the occurrence and prevalence of arbovirus infections depends on the presence of the particular arthropod/vertebrate species that can be infected. Because of this, most arbovirus infections are zoonotic, with humans becoming accidentally infected by an infected vector that usually bites a different vertebrate species. However, in cases when humans are natural hosts and viremia levels are sufficient, arbovirus infections have the potential to become endemic and even epidemic if the arthropod vector is abundant. This is evident in many DENV endemic tropical regions, where the main mosquito vector, *Aedes aegypti*, is highly abundant.

Arboviral Diseases

Arboviral infections can produce a spectrum of infections from asymptomatic and mild febrile illnesses to severe clinical manifestations and disease. For certain arboviruses, severe disease can develop, manifesting as arthritis, encephalitis, or hemorrhagic fever in a minority of patients. Encephalitis and hemorrhagic forms are associated with a high mortality. The development of a clinical illness following an arboviral infection is a result of a complex interaction between viral and host factors. Host factors determine the onset and manifestations of the infection, and as such, follow a temporal sequence with the early clinical presentation often protean in nature. Fever is a universal manifestation of all symptomatic arboviral infections and often the initial clinical presentation. As the illness progresses and the host response matures, classic signs and symptoms present and severe disease may develop. As part of the initial evaluation, an estimate of the day of onset of clinical illness should be determined from the patient where possible based on the first day of febrile illness. The initial date of exposure may not be known and may vary between viruses; however, the incubation period is usually 2–15 days prior to the onset of symptoms, on average. Viremia occurs during the acute phase of illness which is within the first 5–10 days of symptoms appearing.

Early knowledge of exposure and symptom onset can be critical for determining appropriate diagnostic tests, effective treatments and disease control and management, particularly if the threat of more severe disease or further outbreaks exists. Virus isolation and molecular detection of viral nucleic acid by polymerase chain reaction are effective tests early during the viremic phase and can provide a definitive diagnosis. Serology-based technologies can be useful once antibodies appear and levels and types produced (e.g. IgM and IgG) can be dependent on whether the infection is primary or secondary. For serology, it is preferable to compare levels of antibody species between two serum samples tested in parallel, each collected in the respective acute and convalescent phases of illness, approximately 10–14 days apart.

In humans, the clinical syndromes that arboviral infections generally manifest, together with their representative viruses fall into five categories: (1) generalized febrile illness (e.g., chikungunya, O'nyong-nyong, Ross River, dengue (DENV)); (2) fever with rash and arthritis (eg chikungunya, Ross River, O'nyong-nyong) or myalgia (eg DENV); (3) encephalitis (eg JEV, WNV, St. Louis virus (SLV), tick-borne encephalitis (TBEV), equine encephalitis viruses; (4) hemorrhagic fever (e.g., YFV, DENV, Rift Valley fever (RVF), and Crimean-Congo hemorrhagic fever); and (5) congenital microcephaly or Guillain-Barré syndrome (ZIKV). Within a family of viruses, there are generally shared viral factors and thus an overlap of clinical presentations. Understanding the clinical presentations of a family of viruses will aid the clinician in determining the clinical course and etiology of the infection.

Alphaviruses

In the International Committee on Taxonomy of Viruses (ICTV) 2015 release, the genus *Alphavirus* (family *Togaviridae*) consists of 31 virus species. All are transmitted by arthropods and, in general, geographically restricted individually; however, as a genus, they are widely distributed globally. Traditionally, alphaviruses that produce human illness are broadly classified into those that produce rash and polyarthritis and are primarily found in the Old World, and those that produce encephalitis, which are primarily found in the New World.

The alphaviruses associated with polyarthritis and rash include chikungunya virus (CHIKV), O'nyong-nyong virus (ONNV), Igbo Ora virus, Ross River virus (RRV), Sindbis virus (SINV), Barmah Forest virus (BFV), and Mayaro virus. Though geographically diverse, all present with a similar clinical picture. Following the bite of an infected mosquito and a 3–12 day incubation period, a high fever develops with headache, nausea, vomiting, and severe joint pain. A diffuse maculopapular rash develops 4–8 days after the initial illness. Joint pain in the form of arthralgia, can continue for months after the acute illness without evidence of joint damage or arthritis. CHIKV is representative of this family and is widely distributed throughout India, Southeast Asia, and sub-Saharan Africa. It is transmitted to humans by the bite of infected *Aedes* and *Culex* mosquitoes, and primarily by *Aedes aegypti* and *Aedes albopictus*. Mother-to-child CHIKV transmission resulting in severe neonatal encephalopathy has also been documented. First isolated in 1952–53 during an epidemic in Tanzania, CHIKV has emerged from sylvan transmission cycles between nonhuman primates and arboreal mosquito vectors in sub-Saharan Africa to cause human outbreaks of endemic and epidemic polyarthritis throughout Africa and Southeast Asia. To date, the largest known outbreak of CHIKV began in March 2005 in the Indian Ocean islands of Mayotte, Mauritius, Réunion, and the Seychelles. The outbreak strain, belonging to the central/east African genotype, was shown to have mutated during the course of the outbreak, which is believed to have greatly influenced its explosive transmission via *Ae. albopictus*. The mutated CHIKV strain further spread to Sri Lanka and then to neighboring India. By October 2006, there were reports of chikungunya in 151 districts in 8 states/provinces of India, the affected states being Andhra Pradesh, Andaman & Nicobar Islands, Tamil Nadu, Karnataka, Maharashtra, Gujarat, Madhya Pradesh, and Kerala. It is estimated that more than 1.25 million suspected cases have been reported in the country, 752,000 from Karnataka and 260,000 from Maharashtra provinces with some areas reporting an attack rate of 45%. Following an incursion of the Indian Ocean CHIKV strain via a viremic traveler, there was an outbreak in Italy in late 2007, resulting in 205 cases. This represents the first reported cases of CHIKV in Europe, and underscores the potential of this arbovirus to spread to different regions of the world. Whilst this same CHIKV strain continues to cause outbreaks in the Pacific, recent emergence of CHIKV, firstly in the Caribbean in late 2013 and later in the Americas, has surprisingly involved an Asian lineage of CHIKV and *Ae. aegypti* mosquitoes.

O'nyong-nyong is antigenically related to CHIKV and found in East Africa. Outbreaks of ONNV have been reported throughout eastern Africa in Uganda, Kenya, Tanzania, Zaire, Malawi, and Zambia. First isolated in Queensland in 1959, RRV is the most common cause of epidemic polyarthritis in Australia, the disease being first recognized clinically in New South Wales in 1928. RRV is endemic throughout Australia and several Pacific island nations and has caused epidemics in both Australia and Fiji. BFV, like RRV, is another important cause of polyarthritis in Australia. First isolated in the Barmah Forest region in the Murray River Valley of southeastern Australia, it is now recognized as an important cause of fever and arthritis in both eastern and western regions of Australia. SINV was first isolated from Sindbis, Egypt, and is now recognized as one of the most widely distributed alphaviruses causing rash and polyarthritis from Northern Europe to South Africa. In Northern Europe, it is known as Ockelbo in Sweden, Pogosta fever in Finland, and Karelian fever in Russia. Like CHIKV, all the alphaviruses are spread by mosquitoes specific to their geographic region. All produce fever, rash, and acute polyarthritis that can continue for months after the initial infection. A glomerulonephritis has been reported as a potential complication of infection but in general the mortality rate is very low with few deaths reported. CHIKV has been associated with hemorrhagic disease especially in Southeast Asia where it was reported in the 1960s as a cause of hemorrhagic fever in children hospitalized for a presumptive dengue hemorrhagic fever (DHF).

Unlike the alphaviruses that produce arthritis, the alphaviruses associated with human encephalitis occur as a result of spillover from an epizootic episode. Equine and human cases occur through a bridging mosquito vector, and mortality is high in cases of encephalitis in both horses and humans. These alphaviruses include eastern equine encephalitis virus (EEEV), Venezuelan equine encephalitis virus (VEEV), and western equine encephalitis virus (WEEV). Eastern equine encephalitis virus is maintained in an enzootic cycle between ornithophilic mosquitoes, primarily *Culiseta melanura* in North America and passerine birds. Horse and humans are dead-end hosts producing severe encephalitis with 30–40% mortality. In the United States, EEEV has been prevalent in coastal states along the Gulf of Mexico and the Atlantic seaboard, as well as in inland foci in regions near the Great Lakes, including Upstate New York. By contrast, WEEV is distributed in the western plains of the United States and Canada and parts of South America. Enzootic transmission of WEEV is maintained between domestic and passerine birds and its mosquito vector, primarily *Culex tarsalis*. In contrast to EEEV, encephalitis caused by WEEV is associated with a lower mortality of approximately 10% for humans and 30% for horses. VEEV was first isolated in 1934 in Venezuela and found to be the primary cause of equine and human encephalitis in South and Central America, the Caribbean Islands, and the southern parts of the United States including Florida and Texas.

Clinically, EEEV, WEEV, and VEEV all produce similar illnesses with fever, headache, and myalgias as the first presenting symptoms. Encephalitis is associated with severe symptoms of headache and myalgia, along with signs of central nervous system infection including restlessness, neck stiffness, seizures, obtundation, and coma. Focal neurologic defects can develop as cranial nerve deficits and hemiparesis. Laboratory findings can be abnormal with a hyponatremia secondary to a syndrome of inappropriate antidiuretic hormone (SIADH) secretion and cerebrospinal fluid (CSF) consistent with viral encephalitis (high protein, low glucose, high WBC, primarily lymphocytes). Radiographic findings with computed tomography (CT) scan or magnetic resonance imaging (MRI) may demonstrate edema and/or hemorrhage in the thalamus, basal ganglia, and brainstem. Death can occur 2–10 days after the onset of encephalitis. Neurologic sequelae postinfection with seizures or hemiparesis are common.

The different disease manifestations in humans affected by alphavirus infections are believed to be mainly associated with the target tissue where the virus replicates. Thus, alphaviruses that cause rash replicate in the skin, those that cause arthritis replicate in the joints, and encephalitis is associated with virus replication in the nervous system. However, the specific cells that support alphavirus replication in joints are not well characterized; the mechanisms by which alphaviruses that cause encephalitis enter the central nervous system are also not well characterized. Within the central virus system, these viruses replicate in neurons, microglial and oligodendroglial cells. Disease is accompanied by infiltration in the infected tissue of inflammatory cells. These inflammatory cells, while having a role in clearing virus infections, may also contribute to tissue damage and fatal disease.

The severity of disease induced by alphavirus infections is influenced by both host and viral factors. Strains with high susceptibility to type I interferon, one of the first lines of innate immune defense, are in general less virulent. Different viral products from this group of viruses have recently been described to attenuate the type I interferon response, and therefore, are likely to play a role in severity of disease. These include the ns2 protein of Old World alphaviruses, such as SINV, and the capsid protein of New World alphaviruses, such as EEEV. These viral products inhibit expression of cellular genes, including the type I interferon. Another major virulence determinant of alphaviruses that cause encephalitis is their ability to invade the central nervous system, which depends on multiple poorly understood virus and host factors.

Bunyaviridae

The family *Bunyaviridae* is one of the most diverse arboviral families and contains three genera of human-infecting arboviruses: *Orthobunyavirus* (48 distinct species), *Nairovirus* (7 distinct species), and *Phlebovirus* (10 distinct species). *Hantavirus*, an important genus of human disease, is rodent-borne.

Orthobunyaviruses

The genus *Orthobunyavirus* consists of different virus serogroups. The Bunyamwera serogroup includes the representative virus Bunyamwera, and the Cache Valley, Fort Sherman, Germiston, Ilesha, Kairi, and Shokwe viruses. The Bunyamwera viruses are distributed in sub-Saharan Africa, Uganda, Nigeria, and South Africa and produce acute febrile illnesses in humans. Cache Valley virus is the exception to the group and is distributed in the United States, Canada, and Mexico. It produces embryonic and fetal death, stillbirths, and congenital malformations in sheep and other ruminants and a generalized febrile illness with reported cases of encephalitis in humans. The Simbu serogroup viruses are globally distributed and include Akabane, Ingwavuma, and Oropouche viruses. Oropouche virus is the only one of the Simbu serogroup to produce illness in humans and manifests as a generalized febrile illness. Oropouche is found in South America and is responsible for large epidemics of febrile illnesses. It is spread primarily by the biting midge, *Culicoides paraensis*. After a 4–8 day incubation period, fever develops accompanied by joint and muscle pain, severe headache, chills, and photophobia. Rash and meningitis have been described.

The California serogroup viruses all produce encephalitis in humans and are spread by mosquitoes. This group includes California encephalitis, Jamestown Canyon, La Crosse, and Snowshoe hare found in North America; Guaroa in South and North America; and Inkoo and Tahyna in Europe. La Crosse virus is found throughout the northern Midwest and in northeastern United States primarily in the Mississippi and Ohio River basins, with the majority of cases in Wisconsin, Minnesota, Iowa, Indiana, Ohio, and Illinois. Cases from 28 US states have been reported so far. Jamestown Canyon is also widely distributed throughout North

America. All the California serogroup viruses produce encephalitis though disease severity is age-dependent, with La Crosse virus producing more severe disease in children and Jamestown Canyon being more severe in adults. The incubation period is 3–7 days followed by fever, stiff neck, headache, lethargy, nausea, and vomiting. Seizures are a common manifestation and up to 30% can develop a coma. Epilepsy can develop in 10–15% of children, with permanent neurologic disorders in 2%. The California serogroup viruses can be confused with bacterial meningitis since meningitis is a common clinical presentation of infection in the case of these viruses, with both mononuclear and polymorphonuclear cells being found in the CSF. As with the New World alphaviruses, encephalitis is associated with viral invasion of the central nervous system, and with viral replication in neurons and glial cells. La Crosse virus is maintained in nature in a cycle that involves chipmunks and hares as vertebrate hosts and the mosquito vector *Aedes triseriatus*.

Globally, there are a number of other mosquito-transmitted orthobunyavirus serogroups associated with human disease. These are the Anopheles A (Americas), Bwamba (Africa), Group C (Americas), Guama (Americas), and Nyando (Africa) groups. Although not much is known about the determinants of virulence of orthobunyaviruses, the nonstructural protein NSs encoded by these viruses appears to play an important role in virulence by inhibiting host antiviral responses. This is achieved through its ability to inhibit cellular mRNA transcription, preventing host gene expression and dampening the induction of antiviral host genes, such as type I interferon.

Nairoviruses

The *Nairovirus* genus contains two important human pathogens: the Crimean-Congo hemorrhagic fever group, which includes Crimean-Congo hemorrhagic fever virus (CCHFV) and Hazara virus, and the Nairobi sheep disease group, which includes Nairobi sheep disease virus (NSDV) and Dugbe virus. Both CCHF and NSD group viruses are transmitted primarily by ticks though the virus has been isolated from culicoides flies and mosquitoes. CCHFV is widely distributed throughout Central Asia and Africa and NSDV in parts of Africa. Both are maintained in the environment by domestic animals as sheep, goat, and cattle, with humans becoming infected either through the bite of an infected tick or by inoculation from the slaughtering of infected animals. CCHF is transmitted to humans by the bite of infected *Hyalomma* species ticks. Domestic animals serve in the transmission cycle as the viral amplifying host or reservoir. Ticks maintain the virus in the environment and can remain infected for long periods and infect their progeny by transovarial transmission. Risk for human infection primarily involves behavior that increases the potential exposure of bites from infected ticks, handling of infected carcasses, and nosocomial transmission. In a study conducted in northern Senegal, antibody prevalence to CCHFV was similar among the sexes, increased with age, and was related to herding activities, sleeping outdoors, bite by a tick, or contact with sick animals. Abattoir workers are at particular risk. An investigation of an outbreak largely associated with workers in Saudi Arabia and the United Arab Emirates demonstrated both clinical disease and high antibody seroprevalence rates; Pakistan has experienced 13 outbreaks of CCHF since 1976 that were associated with significant nosocomial transmission among health care professionals due to contact with infected body fluids and blood. CCHF in humans is associated with hemorrhagic fever with a 3–7 day incubation period, and the time between the onset of fever to hemorrhagic manifestations is brief. The time from the onset of fever, chills, headache, and muscle pains to the time of severe hemorrhage can be 3 days, with death occurring on the sixth day of illness. Other signs and symptoms associated with CCHF are vomiting, diarrhea, and throat pain. Mortality from CCHF can be as high as 30%, with human to human transmission through contact with infected body fluids responsible for nosocomial outbreaks.

The high mortality rate associated with CCHFV infections and the lack of vaccines and antivirals against this pathogen restrict the research with this virus to laboratories that have high biocontainment facilities (BSL4). In addition, there is no animal model of the disease caused in humans by CCHFV. Thus, very little is known on the molecular determinants of pathogenesis of CCHFV. Recently, a protease domain in the N-terminal region of the viral-encoded RNA polymerase has been characterized and shown to deconjugate ubiquitin and ubiquitin-like molecules from target proteins. Since ubiquitin and ubiquitin-like molecules are involved in many diverse cellular processes, including host defense, it is likely that this viral protease domain disarms host antiviral responses and contributes to virulence. In contrast to CCHFV, which usually causes inapparent infections in vertebrate hosts different from humans, NSDV causes disease in sheep and goats that is associated with virus replication in endothelial cells and necrosis of capillary walls. NSDV has been isolated from febrile patients in Uganda, but its impact on human health is unclear.

Phleboviruses

The genus *Phlebovirus* contains the sandfly fever group, which includes the viruses Candiru, Punta Toro, RVF, sandfly fever Naples, Toscana, sandfly fever Sicilian, and Chagres. Also, there are a number of tick-transmitted human pathogens in the Bhanja group including severe fever with thrombocytopenia syndrome virus (China), Heartland virus (United States of America) and Bhanja virus (Eurasia and Africa) that are associated with acute febrile illness. Most other phleboviruses are transmitted by the phlebotomine sandfly, with the exception of RVFV which is transmitted by *Aedes* species mosquitoes. They are widely distributed throughout the world including the Middle East, sub-Saharan Africa, and Africa.

RVFV is a human pathogen, also of economic importance, that has emerged from Africa to produce epidemics throughout sub-Saharan Africa and the Middle East. RVF is an acute zoonotic disease that infects both ruminant animals and humans. Human infections occur as an epizootic, with transmission occurring primarily from infected mosquitoes (*Culex*, *Aedes*, and *Anopheles* species) and secondarily from the handling of infected animal carcasses. RVFV was originally isolated in 1930 in the Rift Valley of

Kenya, East Africa, and was responsible for over 30 large outbreaks of animal and human disease in East Africa since the 1930s. Age-specific mortality for RVF is greatest for the elderly, 57% ≥ 90 years, 22% in ages 80–89 years, 19% in 70–79 years, with the overall mortality being 14%. RVF produces considerable economic loss among domestic animals and also causes human disease. In a study of 124 patients, the major clinical characteristics for RVF included hepatocellular failure (75%), acute renal failure (41%), and hemorrhagic manifestations (19%). Development of retinitis, unique to RVF, was seen in 16 patients, and 7 experienced meningoencephalitis as a late complication of the disease. A total of 56 patients (34%) died. The development of hepatorenal failure, shock, and severe anemia were all factors associated with patient death. Sicilian, Naples, and Toscana viruses are spread by infected sandflies and are found throughout the Mediterranean basin, the Middle East, and the Arabian Peninsula. Following an incubation period from 2 to 6 days, there is fever and malaise accompanied by headache, photophobia, back and joint pain. Most cases are self-limited though acute lymphocytic meningitis and meningoencephalitis occur in more severe cases.

Like the *Orthobunyaviruses*, but in contrast to *Nairoviruses*, RVFV is known to encode a nonstructural NSs protein. Despite the lack of amino acid identity between the NSs proteins of Bunyamwera and of RVFV, the NSs of RVFV also inhibit cellular gene expression of antiviral genes, including type I interferon. The attenuated clone13 strain of RVFV has a defect on its NSs gene that is associated with viral attenuation, underscoring the importance of the NSs protein of RVFV in its virulence.

Flaviviruses

The family *Flaviviridae*, genus *Flavivirus*, contains a number of important human arboviruses that have both historical and ongoing significance and which have produced large epidemics of disease ranging from severe febrile illnesses to encephalitis and hemorrhagic fever. The *Flavivirus* genus is organized into antigenic groups and includes Kyasanur forest disease virus (KFDV); Omsk hemorrhagic fever virus (OHFV); Powassan virus (POWV); TBEV (European, Far Eastern, Siberian, TBE); Aroa (Aroa, Bussuquara, Iguape, Naranjal); (DENV 1–4); Rio Bravo (Rio Bravo virus); JEV, Murray Valley encephalitis virus (MVE), St. Louis encephalitis virus (SLEV); West Nile (Kunjin virus, WNV); Kokobera (Kokobera virus); and YF (Banzi virus, YFV). All are either tick-borne (KFDV, OHFV, POWV, TBEV) or mosquito-borne (DENV, JEV, MVEV, SLEV, WNV, YFV, and ZIKV). Clinically, the flaviviruses produce a range of symptoms from acute febrile illness to hemorrhagic fever to encephalitis. Most are associated with high morbidity and mortality and are geographically widely distributed. DENV, JEV and WNV have emerged as important human pathogens that have spread geographically in the last 50 years.

Dengue Virus

Dengue fever is the most prevalent mosquito-borne viral disease affecting subtropical and tropical regions of the world. Much of its global spread is attributed to the resurgence of its primary mosquito vector, *Ae. aegypti*. Acute DENV infection can be asymptomatic or manifest in a spectrum of illnesses ranging from a subclinical mild febrile illness, to a more severe non-hemorrhagic illness termed dengue fever (DF), to DHF and dengue shock syndrome (DSS). DENVs have been antigenically classified into one of four individual serotypes (DENV 1–4). Depending on the immune status and other demographic factors of the existing human population and the serotype responsible for the outbreak, the incidence of asymptomatic dengue infections can range from 1.4% to 4.3% per year or approximately 1–2 times the incidence of symptomatic dengue infection. During the initial febrile illness, patients with both DF and DHF present with fever, headache, myalgia, arthralgias, fatigue, and anorexia. Saddle-back fever is typically present and heralds defervescence, onset of rash, and convalescent period in the DF patient. Convalescence can be prolonged and associated with postinfection depression and lethargy. The presenting symptoms of both DF and DHF are similar to other viral hemorrhagic fevers and are often protean in nature. These syndromes are also often difficult to distinguish from each other and other causes of non-dengue febrile illnesses. Common laboratory findings during the initial phase of illnesses for both DF and DHF include leukopenia, mild anemia, mild thrombocytopenia, and elevations in liver function tests. DHF/DSS is the most severe form of acute DENV infection and clinically distinguished from DF by the development of plasma leakage and hemorrhage. The World Health Organization case definition of DHF (requiring all of the following) is as given: fever or a history of acute fever lasting from 2 to 7 days; hemorrhagic tendencies as manifested by a positive tourniquet test or petechiae, ecchymoses, purpura or external bleeding or hematemesis or melena; thrombocytopenia ($100,000$ cells per mm^3 or less); evidence of plasma leakage by a rise in the hematocrit equal to or greater than 20% above average for age, sex, and population or a drop in the hematocrit following volume replacement equal to or greater than 20% of baseline or signs of plasma leakage as demonstrated by pleural effusion, ascites, or hypoproteinemia. Children with DHF prior to the onset of plasma leakage are more likely to manifest higher liver enzyme abnormalities than children with DF and a higher erythrocyte sedimentation rate. The acute febrile phase lasts between 2 and 7 days with hemorrhagic manifestations limited to petechiae hemorrhage or easy bruising. The liver may be enlarged; the spleen is frequently normal and generalized lymphadenopathy may be present. Defervescence is the hallmark sign for impending plasma leakage and the patient is frequently restless with cold extremities. Thrombocytopenia, coagulopathy, and hemorrhage occur during this time period and the onset of shock is acute. Plasma leakage manifests as a pleural effusion, ascites, or swollen extremities and is indicated by an intravascular hemoconcentration and an increase in the hematocrit of greater than or equal to 20% from baseline levels. The World Health Organization criteria define DHF in increasing severity from grades I to IV, with grade I as fever with constitutional symptoms and hemorrhagic manifestation, a positive tourniquet test or easy bruising, to grade IV, with profound shock with undetectable blood pressure or

pulse. Unusual manifestations of DENV infection can occur and include severe hepatitis with jaundice, metabolic acidosis, and disseminated intravascular coagulation producing a hepatic encephalopathy and a Reyes-like syndrome. Encephalitis and a neurological disorder similar to poliovirus infection can also occur during acute DENV infection.

The development of DHF/DSS, the most severe disease manifestation of DENV infection, is well known to be associated with secondary DENV infections. The four different DENV serotypes circulating in nature can inherently complicate the development of disease and clinical outcomes for the susceptible human host. Whilst infection with one serotype confers neutralizing host immunity that protects against reinfection with the same serotype, previous infection with a given serotype can increase the risk of severe disease should a subsequent infection occur with a different DENV serotype. The lack of an animal model of DHF has hampered our understanding of the molecular and immunological mechanisms responsible for this severe clinical manifestation of the disease. Cross-reactive antibodies elicited against the first-infecting DENV serotype are suspected to play a major role in DHF, as they cannot efficiently neutralize a different DENV serotype, but can enhance infectivity by facilitating viral entry in target cells through the Fc receptor. However, DHF is a very complex disease that is influenced by many factors, including previous exposure to a different DENV serotype, viral factors, and host factors, most of which are still poorly understood. The onset of severe clinical manifestations coincides at a time when viral replication and viremia are subsiding, and therefore plasma leakage is probably not caused by direct infection of endothelial cells by DENV. Higher activation of DENV-specific immune cells has been associated with DHF, and the presence of memory cross-reactive T cells elicited by previous infections with a different serotype might have a role in facilitating DHF. Thus increased levels of T cell activation in secondary DENV infections can result in elevated levels of cytokines, chemokines and other host factors that could lead to plasma leakage, platelet dysfunction and DHF. High levels of circulating tumor necrosis factor, soluble tumor necrosis factor receptors, soluble CD8, soluble interleukin-2 receptors, interleukin-10, macrophage migration inhibition factor, interferon-alpha, interferon-gamma, interleukin-13, interleukin-18, CCL2, and complement components 3a and 5a, among other factors, have been correlated with severity of dengue disease. However, the specific contributing role of cross-reactive antibodies and T cells in facilitating DHF is unclear. In addition, several DENV genotypes have also been associated with increased virulence, but the molecular basis for these observations is not completely elucidated. The predisposition that pre-existing immunity against one DENV serotype increases the risk of severe infection with a different serotype is one of the major challenges faced by DENV vaccines. Alternative vaccination approaches are being considered, but essentially, in order for any DENV vaccine candidate to be considered, it will need to provide protective immunity against all four DENV serotypes and not a partial immune response that could predispose toward more severe infection with any of these serotypes. Following several clinical trials, a chimeric, live-attenuated vaccine to all four serotypes has been licensed in a number of endemic countries. Its efficacy in broad-scale field application is yet to be determined.

YFV and Other Hemorrhagic Flaviviruses

YFV is the prototypic virus of the *Flavivirus* genus and, like dengue, produces a spectrum of clinical illnesses from febrile illness to severe hemorrhagic fever. It is also spread by *Ae. aegypti* mosquitoes but, unlike dengue, has been geographically restricted to parts of South America and Africa. Following an incubation period of 3–6 days, illness begins with fever, chills, headache, back and muscle pain, and loss of appetite, nausea and vomiting. Fever can then remit with the patient's symptoms improving within 24 h followed by a reoccurrence of fever, vomiting, epigastric pain, and jaundice. Hemorrhagic illness can then occur with bleeding as hematemesis, melena, petechiae, ecchymoses, and bleeding from the gums. Dehydration and renal failure are potential complications, with death resulting in 20–50% of cases of severe illness. Experimental YFV infection in macaques has given insights on the pathogenesis of this virus. The virus first replicates in lymph nodes, and then spreads to the liver, spleen, bone marrow, and muscle. Infection of the liver and the spleen results in hepatocellular damage and lymphocytic necrosis, respectively. However, the bases of the hemorrhagic manifestations and of renal dysfunction are less understood, and these clinical manifestations are attributed to a generalized circulatory collapse and altered platelet function. YFV infections can be prevented by vaccination, but the disease is still highly prevalent in some areas of the world due to the lack of widespread vaccination.

Other flaviviruses that produce hemorrhagic illness include the KFD virus, which is tick-borne transmitted and geographically restricted to Karnataka state, India. Clinical illness in humans is characterized by fever, headache, muscle pain, cough, gastrointestinal symptoms, and hemorrhage. A biphasic course may develop with fever and hemorrhage lasting 6–11 days followed by an afebrile period of 9–21 days. Fever reappears and a meningoencephalitis may develop. OHFV is also tick-borne and geographically restricted to the Omsk and Novosibirsk areas of the former Soviet Union. Infection is as in KFD, resulting in fever, muscle pain, and hemorrhage. Hearing loss, hair loss, and neuropsychiatric complaints are common.

WNV, JEV, and Other Encephalitic Flaviviruses

Encephalitis is a feature of the TBEV group (European, Far Eastern, Siberian, TBE), JEV group (JEV, MVEV, SLEV), WNV group (Kunjin virus, WNV), and Rocio virus. All differ in their geographic distribution, arthropod vector (ticks for TBEV and mosquitoes for JEV and WNV), but are similar in having complex life cycles, with animal reservoirs including birds in the case of JEV and WNV. Humans are considered a dead-end host.

The clinical syndromes produced by these viruses are similar and range from an acute febrile illness with or without headache, encephalitis, and aseptic meningitis. In general, after a 6–16 day incubation period, clinical illness develops with fever, chills, anorexia, nausea, vomiting, dizziness, and drowsiness. Clinical progression to encephalitis can occur, manifesting with nuchal rigidity, photophobia, altered consciousness, and neurologic signs such as muscular rigidity, cranial palsies, tremors, involuntary

movements, focal or generalized paralysis, and seizures. Atypical presentations can occur with focal lower motor neuron deficits leading to extremity paralysis similar to acute paralytic poliovirus infection. Mortality is high if disease progresses to encephalitis (5–40%), and occurs on the fifth to ninth day of illness. Poor prognostic signs include respiratory compromise, seizure frequency and duration, duration of fever, albuminuria, high levels of viral replication in the brain, and low IgM antibodies in the CSF. Laboratory findings associated with encephalitis are elevation in the CSF pressure, CSF pleocytosis, primarily consisting of monocytes or lymphocytes, low CSF glucose, and high protein. Brain imaging may demonstrate focal inflammation and/or hemorrhage in the thalamus and basal ganglia. Long-term sequelae following acute infection can occur in severe cases and include paralysis, seizure disorder, learning disabilities, mental retardation, and psychiatric disorders. Different viral strains are known to have different levels of virulence, with the best example corresponding to the virulent New York strain of WNV, as compared to the low virulent Kunjin virus strain of WNV. Multiple viral genes are likely to be responsible for differences in virulence. Host factors also play a major role in the outcome of the disease. The elderly are more likely to develop severe encephalitis after WNV infection. Deficiencies in the chemokine receptor CCR5 in humans, associated with resistance to HIV infection, have been correlated with increased incidence of severe WNV infections. During WNV encephalitis, neurons are infected, and immune-mediated damage contributes to the disease. Access to the central nervous system by the virus is an important determinant of disease, and factors that facilitate this process are likely to play a major role in pathogenesis. Interestingly, TLR3, a host factor that helps to trigger cytokine production in response to WNV infection, appears to contribute to disease by inducing tumor necrosis alpha production that in turn increases the permeability of the blood–brain barrier, facilitating viral entry in the brain.

Zika Virus

ZIKV is a flavivirus which is related to DENV, and was originally isolated in the Zika forests of Uganda, Africa, in 1947 from a sentinel monkey. The virus circulates globally in two main lineages: African and Asian. Whilst >80% of infections are believed to be asymptomatic, the disease mostly causes mild dengue fever-like symptoms. However, a recent incursion of an Asian strain of ZIKV into Brazil in 2015 which has led to ongoing transmission and major epidemics in the Americas, has been associated with Guillain-Barré syndrome and an increased risk of congenital microcephaly in babies whose mothers are infected during pregnancy.

Inhibition of Host Antiviral Responses by Flaviviruses

Among the host antiviral responses, type I interferon appears to contribute to control flavivirus infections, as better evidenced by the increased susceptibility to DENV infection of mice deficient in the type I interferon response. Interestingly flaviviruses, as with many other viruses, have also evolved specific mechanisms that contribute to attenuate the type I interferon response, and are likely to play a role in pathogenesis. For WNV and DENV, multiple nonstructural proteins have been shown to have an impact in decreasing type I interferon signaling, most likely allowing these viruses to replicate even in the presence of interferon. The NS5 protein of other flaviviruses, including JEV and TBEV, has been shown to prevent type I interferon signaling by preventing phosphorylation of transcription factors induced by interferon. Another host immune component that is known to be inhibited by flaviviruses, at least in the case of WNV, is the complement system. The nonstructural protein NS1 of WNV has been shown to inhibit complement activation by binding the regulatory protein factor H. This protein is known to be circulating at high levels in the sera of infected patients, and by inhibiting complement-mediated antiviral defenses, is likely to contribute to viral disease. However, many of the specific interactions between the host and the virus that modulate disease outcome are still unknown, and further investigation in this area is needed to uncover the molecular basis of the pathogenesis of arboviruses and to provide with new rational strategies to treat and prevent severe infections caused by this diverse group of viruses.

Orthomyxoviridae

In the family *Orthomyxoviridae*, only the genus *Thogotovirus* is associated with arthropod transmission. Two tick-transmitted virus species are currently recognized: the type species *Thogoto virus* and *Dhori virus*. These viruses are geographically widespread, infect a variety of animal species, and can cause disease in humans.

Reoviridae

This is the only known family of double-stranded RNA virus that is transmitted by arthropods. Of the 15 recognized genera, three (*Orbivirus*, *Coltivirus*, and *Seadornavirus*) are able to cause infection of humans and animals by arthropod transmission. Colorado tick fever virus is a tick-transmitted coltivirus which causes disease in humans. It is found in the western United States of America and Canada.

Archaea: Definition and General Characteristics

Archaea are prokaryotic microorganisms that possess molecular characteristics distinctive from both bacteria and eukaryotes. They were described as a separate domain of life by C.R. Woese and coworkers in 1977 following a comparison of small ribosomal RNAs (rRNA).

Archaea are peculiar in various aspects. While their molecular machineries (replication, transcription and translation) resemble the homologous eukaryotic systems, they possess unique membrane lipids, which are characterized by an isoprenoid hydrocarbon side chain linked via an ether-bond to the *sn*-glycerol-1-phosphate backbone. In contrast to bacteria, their cell walls do not contain peptidoglycan, although some members have pseudomurein. Like bacteria, archaea do not possess organelles or a nucleus, and their ribosomes are 70S-type ribosomes. The DNA of many archaeal representatives is organized with histones similar to eukaryotes. Moreover, while archaea cannot form spores to escape temporarily harmful situations or endure over time, they have been described to be able to grow extremely slowly, or to remain dormant, which allows them to survive for thousands of years under certain conditions.

Similar to bacteria, archaea are metabolically diverse and include both auto- and heterotrophs as well as organo- and lithotrophs. For instance, archaea include methanogens, which produce methane as a major end product of their metabolic activity, a trait which has been described only rarely for fungi or bacteria. On the other hand, currently known members of the Archaea do not include *bona fide* photosynthetic organisms, although some halophilic archaea are able to exploit sunlight for energy-yielding processes.

Originally, archaea have been thought to comprise organisms thriving predominantly in extreme environments (e.g. high-salt, low or high pH, and high temperature conditions), from which numerous archaeal isolates have been obtained. Recent progress in cultivation-independent sequencing technologies has however revealed that archaea are much more widespread and of greater ecological importance than assumed previously. Yet, most of these recently described archaea, which inhabit moderate environments, such as marine or freshwater systems, sediments and soils, or occur in association with other organisms, have so far resisted cultivation.

Until today, many archaea are considered to be specialists in energy exploitation, which are well adapted to nutrient-limiting ecological niches. For example, some members of the Archaea, such as the anaerobic methane oxidizing euryarchaeota, are able to exploit metabolic strategies that operate close to the thermodynamic limit of life. The unique metabolic characteristics of some archaeal groups such as the methanogens place them at the end of complex food chains, where they play a regulatory role in numerous ecological settings.

The Recognition of Archaea as a Separate Domain of Life

Archaea have been known to microbiologists for more than 150 years. The first investigated genera included strictly anaerobic, methanogenic species (methanogens), halophiles that are able to tolerate very high salt concentrations, and hyperthermophilic archaea with optimal growth temperatures above 80°C. It was A. Béchamp who first described the role of microbes in methanogenesis in 1868, a process that is (almost) exclusively associated with archaea today. However, due to their prokaryotic nature, archaea were initially regarded as bacteria and were not recognized as a separate domain of life until the end of the 20th century. The recognition of Archaea is closely linked to the development of molecular classification systems, developed by Carl R. Woese and his co-workers.

Until the 1970s, concepts of taxonomic assignment relied on morphological and metabolic traits, such as differences in the basic morphology and structure of cells. For example, the separation of eukaryotes and prokaryotes was based on the presence and absence of membrane-bound nuclei, respectively. In fact, it was common practice to describe all representatives of ‘small germs’ lacking a nucleus as ‘bacteria’, a scientific term originally introduced by C. G. Ehrenberg in 1838. From this standpoint, it comes as no surprise that the first isolates of archaea were also regarded as bacteria, considering their morphological similarities. Even today this bias is apparent in the nomenclature of archaeal taxa. Since the 1930s, pure cultures of methanogenic archaea were acquired by the microbiologists H. A. Barker, K. Schnellen, and T. C. Stadtman, terming the first methanogens *Methanobacillus omelianskii*, *Methanobacterium formicicum*, *Methanosarcina barkerii*, and *Methanococcus vannielii*. With *Bacillus halobius ruber* and *Bacterium*

halobium, the nomenclature of subsequently isolated haloarchaea also continued to include the stem 'bacterium' in their description of order, family, and certain genera.

The pioneering work of Carl Woese and George Fox in 1977, however, changed the entire view on the diversity of life. For the first time, Archaea were recognized as a major and separate domain of life besides Bacteria and Eukarya. Woese and his colleagues were working on methods to infer phylogenetic relationships by using molecular markers instead of morphological traits or other characteristics that are either subjective or too simplistic for a reliable taxonomic assignment. This was not a novel approach, as biochemists were aiming to infer phylogenetic relationships by analyzing amino acid sequences of proteins such as cytochrome C (Fitch and Margoliash) or blood-clotting fibrinopeptides (Doolittle and Feng). However, the primary problem with the usage of specific amino acid sequences as phylogenetic marker was their lack of universality. Woese and his colleagues on the other hand, focused on a biopolymer that turned out to be highly conserved and a universal and defining feature of cellular life: the ribosomal RNA (rRNA). All cellular life encodes rRNA components (ribozymes), which form, together with ribosomal proteins, the large (LSU) and small subunit (SSU) of the ribosome. The rRNA represents the catalytic center of the protein synthesis machinery, thus carrying out a core process of cellular life. Importantly, the ribosomal RNA and protein components are thought to evolve slowly (as compared to proteins involved in other cellular functions including metabolism) and to be mainly inherited vertically, i.e., from parent to daughter. In particular, the SSU rRNA (also called 16S [prokaryotes] or 18S rRNA [eukaryotes]) turned out to be a suitable phylogenetic marker and was described as "the ultimate molecular chronometer": The nucleotide sequence of the SSU rRNA can be compared and used to infer the evolutionary relatedness of the respective organisms.

Based on the finding that the 16S rRNA of methanogenic organisms not only differed fundamentally from the 18S rRNA of eukaryotes but also from 16S rRNA of bacteria, Woese and Fox proposed the existence of a third domain of life. This domain was originally termed "Archaeobacteria" (Greek *arkhaios*; ancient, antique, primitive), in reference to the suspected antiquity of the methanogenic phenotype. Later, Woese and his colleagues revised the nomenclature to Archaea, as the former terms "Archaeobacteria" and "Eubacteria" (now Bacteria) implied a close but not justified relatedness. They proposed a tripartite tree of life consisting of Archaea, Bacteria, and Eucarya, and thereby provided an important framework for the study of members of the Archaea and the diversity of life.

Archaeal Ecology – From Extremophiles to Symbionts

The predominant isolation of archaea from samples characterized by extreme environmental conditions led to the misconception that archaea mainly comprise extremophilic members. Indeed, representatives of the archaeal domain are still record holders with respect to the highest maximum growth temperature (e.g., *Pyrococcus fumarii* [113°C]) or the lowest pH for growth (e.g., *Picrophilus torridus* [pH 0]). It is assumed that in particular their specific cell wall/membrane architecture allows members of this group to survive and thrive under these extreme conditions. Until to date, the best-characterized archaeal representatives are halophiles, hyperthermophiles and methanogens.

All halophilic (salt-loving) archaea (haloarchaea) belong to the phylum Euryarchaeota and form the class Halobacteria, which includes diverse lineages. Haloarchaea have been isolated from numerous environments, such as shore mud of the Dead Sea (e.g., *Haloferax volcanii*), alpine salt deposits (e.g. *Halococcus dombrowskii*, *Halobacterium noricense*), or salted foods (e.g., *Natrinema pallidum*). Haloarchaea include members with peculiar cell shapes, such as *Haloquadratum walsbyi*, a square-shaped, flat archaeon. Notably, this archaeon had been discovered more than 20 years before its successful cultivation in 2004. All haloarchaea require high salt concentrations for growth. Most species grow optimally above concentrations of 15% salt, and even lyse at concentrations below 10%. Moreover, they are resistant to a number of physical and chemical stressors, such as low water activity, desiccation and low nutrient availability. They depend on organic matter as a carbon source, and some use bacteriorhodopsin for a light-driven synthesis of ATP. It has been reported, that some haloarchaea have survived millions of years in salt-rich sediments, however, contamination by extant microorganisms could not be completely ruled out. Members of the *Natronomonas* genus are multi-extremotolerant/philic, as they withstand not only extremely high salt concentrations, but also high pH (e.g., in soda lakes in Africa).

Methanogenic archaea are a diverse and polyphyletic group of microbes with different (growth) characteristics that include psychrophiles and hyperthermophiles, many of which are widespread in anoxic environments (such as sediments and bogs, as well as the gastrointestinal tract of cattle, termites and many other holobionts). By definition, their metabolism results in the formation of methane gas, which represents a potent climate gas contributing to global warming. It has been predicted, that the melting of permafrost areas (25% of Earth's terrestrial surface) will further increase methane production by methanogens residing in these areas. Methanogenic archaea can use a variety of different carbon substrates, including carbon dioxide, methyl or other C1 compounds, but also acetate. Notably, many members of this group exist in syntrophy with bacteria, living off the products of the bacterial partners and supporting fermentative processes by lowering hydrogen partial pressures inhibiting for many other microorganisms.

Hyperthermophiles are defined as microorganisms with optimal growth temperatures above 80°C. The best characterized hyperthermophiles in the archaea belong to the phyla Euryarchaeota and Crenarchaeota. Many members of these groups have

been isolated from volcanic solfatar fields, hot springs or hydrothermal vent systems from Iceland, Italy, Japan, US, Russia and many other places. They either grow chemolithoauto- or chemolithoheterotrophically on a number of geologically important substances such as sulfur and nitrogen compounds.

The upper limit of growth is highly debated. *Pyrolobus fumarii*, isolated from a black smoker hydrothermal vent was described to actively divide at 113°C in 1997, ceasing growth at temperatures below 90°C. Other studies report metabolic activity at 121°C (Strain 121, *Geogemma barossii*) or even 122°C (*Methanopyrus kandleri*, under specific cultivation conditions). In general, growth at higher temperatures is accompanied by adaptations of various biomolecules, such as preferred use of a certain amino acid composition for the stabilization of proteins (for increased number of disulfide bonds, larger hydrophobic core), an increased proportion of tetraether lipids in the membranes and increased protection of DNA.

First indications about a more global distribution and role of archaea in non-extreme environments were obtained from 16S rRNA gene-based surveys that revealed a high archaeal abundance in cold sea water. In 2001, Karner et al. reported on the archaeal dominance in the mesopelagic zone of the Pacific Ocean, and thereby opened a series of discoveries indicating an archaeal omnipresence in all biotopes on Earth. The universal distribution of archaea was recently confirmed by results derived from the direct sequencing of DNA isolated from various microbial communities. Currently, 250,000 archaeal 16S rRNA gene sequences from a large diversity of environments are available in curated databases such as SILVA (2019). In contrast, only approximately 120 archaeal genera have been cultivated and validly described thus far (source: see “Relevant Website section”). The NCBI Genome database and the JGI Gold (genomes online database) currently host more than 1500 entries for complete archaeal genomes, with overwhelming predominance of Euryarchaeota (in particular Halobacteria, Methanomicrobia), Crenarchaeota (Thermoprotei) and Thaumarchaeota sequences. However, the majority of the recently sequenced archaeal genomes (often represented by metagenome bins or single amplified genomes) originates from uncultivated representatives. To put this into perspective: more than 100,000 bacterial genomes have been generated until today, the majority of which are derived from uncultivated organisms as well.

It is meanwhile well accepted that archaea represent a considerable fraction of Earth’s ecosystems, and it is estimated that they comprise approx. 10%–30% of all microbial life. Notably, archaea seem to be particularly abundant in subsurface ecosystems, in which they have been predicted to be involved in carbon fixation or organic compound turnover. However, most of these taxa are uncultivated and only (partial) genomic information is available. Archaea also play an important role in soil, marine and freshwater systems. For instance, the phylum Thaumarchaeota comprises aerobic ammonia-oxidizing archaea, which have an important role in the global nitrogen cycle. The activity of members of this group in soil environments has direct impact on the available nitrogen content of agricultural ecosystems. Thaumarchaeota, however, have also been found in anoxic and acidic, thermophilic and iron/sulfur-rich sediments.

Furthermore, numerous archaea have been found to be involved in symbiotic interactions. For instance, they can be part of microbial syntrophic communities (such as the anaerobic methane oxidation consortium) and complex microbiomes of sponges, ruminants or plants. Notably, archaea have recently even been detected in the human microbiome, in which they may comprise up to 10% of the microbial community in the gastrointestinal tract and on skin. Due to methodological limitations, the archaeal fraction of the microbiome (the archaeome) remains poorly characterized, although the presence of methanogenic archaea in the human gut has been known for decades. Methanogenic archaea are important components of the human gastrointestinal tract, as they support bacterial fermentation processes by acting as a sink for hydrogen, CO₂, and methyl compounds. Curiously, pathogenic archaea have not been identified thus far, but involvement in pathogenic processes cannot be excluded.

Notably, archaeal parasites that depend on other archaea for growth are however known. For instance, the ultrasmall archaeon *Nanoarchaeum equitans* lives on the surface of its archaeal host *Ignicoccus hospitalis* and is not able to proliferate independently. *N. equitans* and related lineages assigned to the DPANN archaea (see below), have a limited metabolic gene repertoire and lack various genes that encode enzymes of diverse anabolic and catabolic pathways (e.g., carbon, amino acids, lipid, nucleoside, and/or vitamin metabolism). This suggests that various members of this group may depend on microbial or eukaryotic partners to acquire essential metabolites.

Due to their peculiar characteristics, selected halophilic and methanogenic archaea serve as microbial models for the exploration of the limits of life and the assessment of whether life could exist outside of Earth. For instance, brine streamlets were detected on the surface of Mars, fueling the debate on whether halophilic microorganisms could potentially thrive therein. Furthermore, the presence of methane in the Martian atmosphere has raised the question whether methanogenic archaea could represent a biogenic source of this gas. In these regards it is interesting to note, that several halophilic archaea have been shown to be able to survive exposure to space conditions, when shielded against direct radiation, and the ongoing ExoMars mission (orbiter 2016 and lander 2020) aims to track methane production and search for signs of (archaeal) life (Fig. 1).

Archaeal Taxonomy and Evolution

Recent progress in the use of cultivation-independent sequencing methods, such as metagenomics and single cell genomics, has revealed a large diversity of additional archaeal lineages that significantly expand the phylogenetic tree of archaea (Fig. 2). While initial trees only included two potential major archaeal divisions, namely the Euryarchaeota and Crenarchaeota, various additional

Fig. 1 Archaeal biotopes. Color intensity of the circles indicate high salt content (yellow), temperature (red), oxygen content (blue), moderate conditions (green) and symbiosis (purple). Biotopes (from top, clock-wise): Terrestrial volcanic areas (Grand Prismatic Spring, Yellowstone National Park); aquatic environment (freshwater streamlet); soil; mammalian anaerobic gastrointestinal tract; bog; hydrothermal vents in deep-sea marine trenches; and hypersaline aquatic environments (salt pans). lineages of high taxonomic rank have been added recently. The domain Archaea is now thought to be comprised of the Euryarchaeota, the TACK superphylum or Proteoarchaeota as well as the DPANN and Asgard archaea.

The Euryarchaeota likely forms two major sub-divisions both of which comprise a diversity of archaeal lineages including the previously cultivated methanogens, hyperthermophiles and halophiles. The TACK archaea include in addition to the Thaumarchaeota, Aigarchaeota, Crenarchaeota and Korarchaeota, a variety of recently proposed phylum- or order-level lineages, such as for example the Bathyarchaeota, Geoarchaeota, Geothermarchaeota, Verstraetearchaeota and Marsarchaeota (Fig. 2). The Asgard archaea represent a group with currently four recognized sub-lineages referred to as the Loki-, Thor-, Odin- and Heimdallarchaeota (Fig. 2). Finally, the DPANN (originally an acronym for Diapherotrites, Parvarchaeota, Aenigmarchaeota, Nanoarchaeota, and Nanohaloarchaeota) includes a large variety of sub-lineages many of which comprise organisms with small cell and genome sizes. The cellular and genomic features of members of these DPANN archaea, which include known ectoparasites such as *Nanoarchaeum equitans* (see previous paragraph), comprise putative host dependent organisms.

While the taxonomy and exact phylogenetic placement of these archaea as well as the root in the archaeal tree is still debated, the investigation of the genomes of these only recently described lineages has unveiled many interesting details about the metabolic potential of archaea as well as widened our perspective on their role in key evolutionary events. First of all, it was recently shown that the hallmark enzymes involved in methanogenesis and methane oxidation, previously thought to be exclusively found in few members of the Euryarchaeota, are encoded in the genomes of various additional archaeal lineages, including in representatives of the TACK archaea. This much broader distribution of methanogenesis marker proteins has reinvigorated discussions on the early evolution of archaea and raised the possibility that the last archaeal common ancestor (LACA) may have been an anaerobic chemolithoautotroph that used the Wood-Ljungdahl pathway for carbon fixation and methanogenesis for energy generation. Yet, the patchy distribution of the key enzymes of these pathways in archaea points towards a complex evolutionary history involving several independent gene losses as well as horizontal gene transfers. Furthermore, the evolutionary origins of the potentially deep-branching DPANN archaea, many of which have very restricted metabolic gene sets and do not encode enzymes involved in methanogenesis, remain to be investigated.

Fig. 2 Schematic tree representing major currently recognized lineages of the Archaea. The tree has been adapted and modified from a phylogenetic analysis generated using a maximum likelihood approach implemented in IQ-tree (model of evolution: LG + C60) with an amino acid alignment consisting of 34 conserved marker proteins. The relationship of the various different lineages to each other is poorly established and deeper nodes are therefore represented by dashed lines. Furthermore, the exact placement of various lineages such as Altiarchaeota and Methanonatronarchaeia is currently unresolved. For instance, the asterisks point out two alternative placements recently suggested for the Methanonatronarchaeia.

Further interesting insights into a key evolutionary event came from the discovery of the Lokiarchaeota, which themselves were subsequently shown to belong to the Asgard superphylum. The Asgard archaea are currently known to include the four major archaeal lineages, referred to as the Loki-, Thor-, Odin-, and Heimdallarchaeota, all of which were named after figures of the Norse mythology. The first genome of a member of the Lokiarchaeota has been obtained from sediment samples taken from about 3300 m below sea level in proximity to the active venting site Loki's Castle, while additional genomes of members of this group have been reconstructed from metagenomes derived from sediment samples all over the world. Notably, phylogenetic analyzes of a set of marker genes has suggested that Asgard archaea may represent the closest archaeal sister lineage of Eukaryotes. Furthermore, members of these archaea were shown to contain several so-called eukaryotic signature proteins (ESPs), i.e., proteins that have not previously been found in archaeal or bacterial genomes but represent important components of eukaryotic proteomes or proteins that are most similar to eukaryotic homologs. Altogether, these findings support the hypothesis that eukaryotes evolved from a host cell of archaeal decent and an alphaproteobacterial symbiont. In this respect, Archaea and Bacteria may be regarded as primary domains of life, while eukaryotes form a secondary domain of life. However, the origin of the eukaryotic cell and the nature of the tree of life remain a matter of ongoing debate and subsequent research will be needed to further unveil the relationship of the major divisions of life.

Genomic and Molecular Characteristics of Archaea

In 1996, Craig Venter and co-workers reported the first full genome sequence of the archaeon *Methanocaldococcus jannaschii* (formerly *Methanococcus jannaschii*), only one year after the completion of the first bacterial genome (*Haemophilus influenzae*). Similar to bacterial genomes, archaeal genomes are characterized by the presence of a main circular chromosome, with high gene

density, and short intergenic spaces. Besides the circular chromosome, some archaea also contain plasmids, which can be transferred from one cell to another.

Although bacterial and archaeal genome architectures appear overall similar, some general differences can be found. For instance, the proportion of the genome containing intergenic regions is consistent across different genome sizes in bacteria, whereas larger archaeal genomes possess a greater proportion of intergenic regions. Additionally, the range of archaeal genome sizes is much narrower than that of bacteria (0.11 Mb, *Nasuia deltocephalinicola* to 16.04 Mb, *Minicystis rosea*). Within archaea, the smallest genomes are found in the DPANN superphylum (~0.5–1.5 Mb) with *N. equitans* having a reduced genome of only 0.49 kb in size (550 protein coding genes). Overall, DPANN genomes are characterized by a high coding density and few pseudogenes, which is in contrast to the small genomes of bacterial symbionts. *Methanosarcina acetivorans* possesses the largest completed archaeal genome (5.75 Mb) known to date (4528 protein coding genes). This methanogenic archaeon is ecologically widely distributed, and has a complex cell morphology and life style.

Microorganisms may be seen as highly integrated self-sustaining metabolic entities (the phenotype), and it remains to be elucidated how these entities are controlled by their underlying genes (the genotype). An important link between these two types is the information processing system of a cell. The process of archaeal replication was already studied for a long period of time, due to the superior (thermostable) properties of archaeal DNA polymerases and their biotechnological application for PCR (e.g., *Pfu* from *Pyrococcus furiosus*) and DNA sequencing (specific variants of *Thermococcus* sp. 9°N PolB DNA polymerase) as well as their high capacity for DNA repair even under extreme conditions.

Besides the family B DNA polymerase and the primase, archaea share many other components of the replisome with eukaryotes, many of which are not homologous to the bacterial counterparts, such as the replicative minichromosome maintenance (MCM) helicase, proliferating cell nuclear antigen (PCNA)-like DNA sliding clamp, Orc/Cdc6-like initiation complex, and replication factor C (RFC). Thus, the archaeal replication apparatus is more similar to the one of Eukaryotes and, due to its simplicity, has been extensively studied as a surrogate to understand the basic mechanisms of eukaryotic DNA replication.

The archaeal transcription apparatus is likely to resemble the ancestral version of the eukaryotic RNA polymerase II (RNAPII). The core contains five universally conserved subunits (Rpo1, 2, 3, 6 and 11) and includes almost all critical elements for transcription. In contrast to Bacteria, which use sigma factors to initiate transcription, Archaea need three general transcription initiation factors: TBP (TATA-binding protein), TFB (Transcription Factor B) and TFE (Transcription Factor E). These initiation factors are homologous to eukaryotic TBP, TFIIB and TFIIE, respectively. Finally, these promoter elements include a TATA-box, B-recognition (BRE) and an initiator (Inr) element on sequence level to initiate the transcription process.

Insights from archaeal genomes have revealed that archaea represent a much more genetically versatile group of organisms than assumed previously. Horizontal gene transfer (HGT) represents a major source of innovation in the evolution of bacterial and archaeal genomes and seems to have had a significant impact in the evolution of some archaeal lineages. In particular, gene acquisitions from bacteria may have contributed to the adaption of various archaeal lineages to a larger variety of habitats and lifestyles and thereby aided in the diversification of the archaeal domain of life.

Archaeal Cell Structure

The basic cell morphology of archaea is comparable to that of bacteria and varies from rods, cocci, spirals to irregular shaped cells. The total cell volume ranges from 0.5 to 2.5 μm^3 , which is ideal for maximizing the surface area-to-volume ratio, optimizing the exchange of nutrients and reaction products via diffusion.

Coccoid cells are found within the Desulfurococcales, whereas lobed cocci are characteristic for members of the Sulfolobales as well as for *Nitrososphaera viennensis*. Members of the genera *Thermoproteus*, *Pyrobaculum* (Crenarchaeota) and *Methanothermus* (Euryarchaeota) depict short rods with a length in the range of usually 2–5 μm . In contrast, rod-shaped *Thermofilum* cells can exhibit a length of up to 100 μm with a diameter of just 150 nm. *Methanospirillum* (as the name already indicates) as well as *Methanosaeta* form long spiral chains. *Picrophilus*, *Hyperthermus* or the ultraflat cells typically found in *Pyrodictium* species are characterized by pleomorphic cell shapes. *Haloquadratum walsbyi*, is remarkable in that it forms an almost perfect quadrate flattened cell. An overview of different archaeal cell structures and morphologies is given in Fig. 3.

All known archaea are surrounded by a cytoplasmic membrane, which is composed of variations of di- or tetra-ether lipids. Apart from members of the Thermoplasmatales, which do not harbor a cell wall, the majority of archaea described so far have a variety of cell walls or surface layers. For instance, the S-layer, which is characteristic for the cell walls of members of the Desulfurococcales and the Sulfolobales, is often composed of just one protein, which self-arranges in a 2D-pseudocrystalline lattice with p1-, p2-, p3-, p4- or p6- symmetry on the cell surface and which is usually anchored in the cytoplasmic membrane or another cell wall component.

Other cell wall types such as pseudomurein (polymeric analog of murein found in bacteria), glutaminyglycan, halomucin or simple protein sheets are present in methanogens and halophiles. Finally, some archaeal representatives such as *Ignicoccus hospitalis* as well as *Methanomassilicoccus luminyensis*, *Cand.* Altiaarchaeum hamiconexum, or the ARMAN archaea have two membranes. With an inner and outer(most) membrane, they resemble the architecture of the Gram-negative cell wall.

Similar to bacteria, there are also several different cell appendages described in archaea. While archaea do not encode flagella homologous to those of bacteria or eukaryotes, they have a functional counterpart referred to as the archaeal flagellum or

archaellum. These archaeal flagella have a diameter of 10–14 nm and show high similarities to bacterial and archaeal type IV pili. Further cell appendages include pili or fimbriae, as well as the grappling hook-bearing hami (Fig. 4), cannulae and fibers.

Biotechnological Applications of Archaea

Archaea are considered an excellent source for nano-/biotechnological applications. Due to their specific biological features, they serve as interesting and valuable tool box for e.g., novel biopolymers and extremozymes. However, only a few aspects of the archaeal biology have thus far been exploited, which to some extent is due to the lack or inefficiency of hosts for gene expression.

Extremozymes are enzymes from microbial extremophiles. For instance, these include the *Pfu* DNA polymerase, which was isolated from the hyperthermophilic archaeon *Pyrococcus furiosus*. The *Pfu* polymerase has a high fidelity at high temperatures, a

Fig. 4 *Cand. Altiarchaeum hamiconexum* (coccioid cell) with cell appendages (“hami”) for attachment (here: bacterial cell) (scanning electron micrograph, bar: 200 nm; credit: Gerhard Wanner), and grapple-hook bearing hami in higher magnification (upper picture, transmission electron micrograph, bar: 100 nm).

precise proof-reading ability, a low error rate, a high-processivity, and a high extension rate, resulting in more efficient DNA target amplification when compared to the traditional *Taq* polymerase. Numerous additional archaeal DNA polymerases have been isolated and are being engineered. Other enzymes of interest include DNA and RNA ligases as well as amylases, proteases and lipases, which among others find applications in the beer and paper industry.

In addition, archaea are of relevance with regard to their photopigments and in the production of biogas (methane), ethanol and polyhydroalkanoates (for medical plastics). Some of their unique cellular features, such as the hami (nano-grappling hooks), could prove useful for nanobiotechnology while their liposomes and cell wall compounds are exploited in the development of vaccines. Finally, archaea are being used for metal biooxidation and biomining. The recent finding that archaea (such as *Cand. Nitrosocosmicus oleophilus*) can have positive impact on plant growth and trigger the systematic resistance in *Arabidopsis thaliana* have raised interest in agricultural applications as well. There, archaeal activity could support fixation, solubilization or mobilization of nutrients, growth hormone production or protection in general.

Viruses of Archaea

Archaea are associated with an extremely diverse virosphere. The vast majority of isolated archaeal viruses infect hyperthermophiles and halophiles from the phyla Crenarchaeota and Euryarchaeota, respectively. However, a handful of viruses has also been described for methanogenic archaea.

Archaeal viruses are currently classified into 18 families, whereas several additional virus groups await official classification. Informally, archaeal virus diversity can be categorized into archaea-specific and cosmopolitan fractions (Fig. 5). The archaea-specific viruses, by definition, are unique to archaea and in their genomic and morphological features do not resemble viruses of bacteria or eukaryotes. Most of these viruses infect hyperthermophilic archaea and are characterized by unique virion morphologies such as bottles (family *Ampullaviridae*), spindles (e.g., family *Fuselloviridae*) or droplets (family *Guttaviridae*). Specific to archaea are also viruses with ovoid, coil-shaped and pleomorphic virions. By contrast, the cosmopolitan archaeal viruses, such as head-tailed viruses of haloarchaea and methanogens, are structurally and genomically related to bacterial (tailed phages of the order *Caudovirales*) and eukaryotic (*Herpesvirales*) viruses.

All archaeal viruses identified thus far carry DNA genomes, which can be either linear or circular. The majority of viruses have double-stranded genomes, although single-stranded (ss) genomes have also been characterized. Notably, a virus with the largest ssDNA genome among all known ssDNA viruses infects a hyperthermophilic archaeon, *Aeropyrum pernix*. Comparative genomics analyses have shown that ~75% of archaeal virus genes do not have homologs in sequence databases (outside of related viruses), whereas some archaeal virus genomes remain completely refractory to functional annotation based on sequence analyses. Thus, archaeal virus genomes represent a rich source of unknown genes, which may underlie unique mechanisms of virus-host interactions and could possess unexpected properties useful for biotechnological applications.

Fig. 5 Viruses of archaea. Archaea-specific and cosmopolitan archaeal viruses are shown in light yellow and gray backgrounds, respectively. The schematics of virion morphologies are shown next to the corresponding family names. * – members of the order *Caudovirales*; # – members of the order *Ligamenvirales*.

Archaeal viruses have evolved a range of mechanisms for efficient penetration of the cell envelope, subversion of the cellular machineries for viral genome replication and expression as well as virion assembly and release. Although some of the stages of the reproduction cycles are likely to mechanistically resemble those of viruses infecting bacteria and eukaryotes (especially in the case of cosmopolitan viruses) other aspects have evolved in the context of archaeal cells and are unique to archaeal virus-host systems. For instance, enveloped viruses, such as fuselloviruses, are assembled and released via a budding mechanism highly similar to that employed by enveloped eukaryotic viruses such as HIV-1 and Ebola virus. By contrast, rod-shaped virions of rudiviruses and icosahedral virions of turriviruses are assembled inside the cytoplasm and are released through pyramidal portals.

Although for most environmentally widespread and ecologically important archaeal lineages, such as Thaumarchaeota, viruses are yet to be isolated, metagenomics and single-cell genomics studies have shown that these archaea are also associated with a diverse virome. Importantly, it has been demonstrated that virus-mediated turnover of archaea, primarily thaumarchaea, in surface deep-sea sediments accounts for up to one-third of the total microbial biomass killed, resulting in the release of ~0.3–0.5 gigatons of carbon per year globally. Thus, archaeal viruses are not mere curiosities of the viral world, as has been considered previously, but are prominent players in the biosphere, with measurable impact on global biogeochemical cycles.

Archaea – Quo Vadis?

During the last four decades, Archaea moved into the spotlight of modern microbiology. Their wide distribution in Earth's ecosystems, their involvement in processes of global relevance, their unique properties and their role in the evolution of cellular life are increasingly recognized. In this article, a number of archaeal peculiarities have not been addressed, which include their complex cell division, or the presence of CRISPR-Cas. Furthermore, numerous questions remain to be answered in future, including the role of Archaea in (human) health and disease, and as components of microbiomes in general. The field of archaea research is still young and dynamic, and many surprises and critical insights can be awaited.

Glossary

Archaea Unicellular microorganisms lacking a nucleus (prokaryotic) that are one of the three primary Domains of life. Cultivated members, such as hyperthermophiles, extreme halophiles and methanogens, are often from extreme environments although their distribution in nature is actually cosmopolitan.

Methanogen One of the major subgroupings of Archaea, methanogens are strict anaerobes that produce methane gas as an end-product of their metabolism.

N-linked glycosylation The attachment of oligosaccharides to proteins specifically at asparagine residues that are found within the sequence asparagine- any amino acid except proline-serine/threonine.

Signal peptide A short stretch of amino acids initially present at the amino terminus of a secreted protein that helps to guide it to its final destination outside of the cytoplasm. During transport across the cytoplasmic membrane, the signal peptide is removed through the action of a signal peptidase.

Sulfolobus A genus of Archaea found often in acidic hot springs that grows at elevated temperatures and low pH (thermoacidophile).

Type IV pili Surface appendages widespread in bacteria and archaea that can be used for attachment or, in bacteria, for a type of motility across solid surfaces called twitching.

Introduction

Archaea are prokaryotic organisms that were originally thought to be unusual extremophilic bacteria. Now, based on the pioneering studies of small ribosomal RNA by Carl Woese in the 1970s it is believed that Archaea represent a third Domain of life, in addition to Bacteria and Eukarya. While prokaryotic like Bacteria, they share certain traits with Bacteria, other traits with Eukarya and have a number of fundamentally unique attributes in addition to their signature 16S rRNA features. It is now known that Archaea are not limited to the extreme environments like hydrothermal vents, hypersaline niches and solfataras where they were originally isolated but are found in most “non-extreme” environments in which they have been looked for. The major cultivatable archaea include extreme halophiles (capable of growth in concentrated NaCl), methanogens (extreme anaerobes), thermoacidophiles (growth at 60–80°C and pH 2), hyperthermophiles (capable of growth in excess of 100°C) and ammonia-oxidizing organisms.

The three Domains of life all contain members that are motile by cellular appendages that were all known previously as flagella, despite the fact that the organelles from eukaryotes, bacteria and archaea are unrelated to each other and only share the one common trait of providing swimming motility to the cells. Unexpectedly, data accumulated on the archaeal appendages revealed their uniqueness compared to bacterial flagella (as outlined below) and, to denote the fundamental difference between the two prokaryotic motility structures, we proposed in 2012 that the archaeal organelle be given a unique designation. We proposed archaeellum (pl. archaeella), a fabricated name that importantly allowed for use of terms analogous to ones employed by bacterial flagella researchers. Thus, archaea possessing these organelles are called archaeellated cells and the main structural proteins of the archaeellum are archaeellins.

The Archaeellum is a Rotating Type IV Pilus

A large bank of data all clearly pointed to the two prokaryotic swimming organelles being distinct, evolutionarily unrelated organelles and that the archaeella were not just unusual adaptations of the bacterial flagella structure to cope with the extreme environments that archaea often inhabit. It became apparent that archaeella were not homologous to bacterial flagella but, quite unexpectedly, homologous to type IV pili systems common in bacteria and archaea (Table 1). While archaeal type IV pili are involved primarily in adhesion and biofilm formation, they are used in bacteria for additional processes such as DNA transfer and a kind of surface motility called twitching. Key points that indicate that archaeella are not a modified version of bacterial flagella come from bioinformatic, biochemical, structural and genetic studies. As sequenced genomes for archaea became available, it could be shown that none of them contained genes associated with the bacterial flagellum structure. Additionally, while archaeella and bacterial flagella are both rotating organelles, the energy source to drive rotation differs fundamentally in the two systems: Bacterial flagella utilize the energy in ion gradients (i.e., either the proton-motive force or less frequently the sodium-motive force) to drive

Table 1 Major similarities and differences of archaeella, bacterial flagella and type IV pili

Trait	Archaeella	Bacterial flagella	Type IV pili
Filament diameter	10–14 nm	18–22 nm	6 nm
Filament structure	No central channel	Central channel	No central channel
Growth point	Base	Distal tip	Base
Anchoring structure	Ill-defined, knoblike	Basal body, rod and rings	None observed
Major structural proteins	Usually multiple archaeellins, some minor	Typically single flagellin, sometimes multiple	One major pilin, several minor
Signal peptides	Class III type on archaeellins	None on flagellins	Class III type on pilins
Signal peptidase for subunit processing	FlaK/PibD (homologue of type IV pilus PilD)	None	PilD (homologue of FlaK/PibD)
Glycosylation	N-linked to archaeellins is common, O-linked rarely	O-linked to flagellins, but rare	O-linked to pilins
Main functions	Swimming, adhesion	Swimming, adhesion	Surface motility (twitching), adhesion
Mechanism of movement	Rotation, switchable	Rotation, switchable	Extension/retraction of pilus
Energy for movement	ATP	H ⁺ /Na ⁺ gradient	ATP
Genes	Some homologs to type IV pilus genes, none to bacterial flagella genes	Assembly system is homologous to type III secretion systems	Some homologs to archaeella genes, not to bacterial flagella genes
Interaction with chemotaxis system	In some archaea, mainly Euryarchaeota	Yes	Sometimes

rotation while archaeella use ATP hydrolysis. Finally, archaeellins are almost universally modified by attachment of N-linked glycans, a posttranslational modification not found in bacterial flagellins but one that is key for archaeellation and motility.

While these data indicated what archaeella were not (i.e., bacterial flagella), other data began to accumulate that showed what they were; i.e., structures homologous to type IV pili. Key to this was the realization that archaeellins, the main structural proteins in the archaeum filament were initially made with N-terminal signal peptides that had to be cleaved from the archaeellins in an essential step for archaeellins to assemble into filaments, while bacterial flagellins are never made as preproteins. The signal peptides of archaeellins were, in themselves, atypical in being usually very short and with overall similarity to signal peptides found in type IV pilins. In type IV pilin systems, signal peptide cleavage is the function of a dedicated signal peptidase called prepilin peptidase (or signal peptidase III). Different archaea were shown to possess a homologue of the prepilin peptidase (designated FlaK or PibD depending on the species) that carried out signal peptide removal from archaeellins and this enzyme was necessary for archaeellation. Analysis of archaeellins themselves showed amino acid sequence similarity in the mature N-terminus to the same region in type IV pilins, a conserved hydrophobic region important for subunit-subunit interaction in the assembled structures. In addition, other genes in the *fla* operon required for archaeellation were clear homologs to genes important for type IV pilus assembly. These archaeal genes were *flaI* and *flaJ*. FlaI is a homologue of ATPases necessary for the incorporation or removal of pilin subunits from the base of the structure, a process that results in extension or retraction of the pilus from the cell surface. FlaJ is a conserved cytoplasmic membrane protein homologous to a type IV pilin protein that interacts with the pilin ATPases to form a platform for pilus assembly.

The type IV pilus-like characteristics of the archaeum led to the prediction that archaeella were assembled by a type IV pilus-like mechanism. A key important piece of supporting evidence for this assembly model was the first 3D reconstruction of the archaeum structure which was shown to share features with the type IV pilus and, most importantly for assembly model predictions, demonstrated that archaeella did not possess a hollow centre that would allow the passage of archaeellin subunits. In bacterial flagella growth, flagellins, made without signal peptides and with the aid of a flagellum-specific type III secretion system located at the flagellum base, enter the lumen present in the flagellum, travel through this lumen to its distal tip and incorporate here under a filament capping protein complex. Thus, the lack of a central channel in archaeella seemingly ruled out any possibility that the assembly of new archaeellin subunits could occur at the distal tip. The proposal of incorporation of new subunits at the base of the archaeum was a radical idea for a prokaryotic “flagellum”. The idea of the archaeum as a rotating type IV pilus was thus supported, although this idea is likely a simplification as more structural data about the archaeum motor was later revealed (see below).

Distribution

Motility is a very common attribute of members of all the well-studied archaeal phyla, including Euryarchaeota, Crenarchaeota, Thaumarchaeota and most recently Nanoarchaeota, a phylum composed of very small obligate symbionts or ectoparasites. With the exception of gas vesicles which allow movement of a limited number of archaeal species by floating, the sole motility apparatus described for archaea is the archaeum. Non-archaeellated cells are always non-motile. The large number of archaea that grow at low pH and/or high temperatures (even above 100°C) and have archaeella attest to the extreme stability of these structures. Many different arrangements as well as number of archaeella have been reported depending on the species (Fig. 1). Some species may

Fig. 1 Electron micrographs showing archaeella in two model organisms, *Sulfolobus acidocaldarius* (A) with a single archaeellum and *Methanococcus maripaludis* (B) with many archaeella. (B) is from Ding, Y., Uchida, K., Aizawa, S.I., et al., 2015. Effects of *N*-glycosylation site removal in archaeellins on the assembly and function of archaeella in *Methanococcus maripaludis*. possess only 1 or 2 archaeella (e.g., *Sulfolobus acidocaldarius*) while others can have upwards of 50 (e.g., *Methanococcus voltae*, *Methanocaldococcus villosus* and *Pyrococcus furiosus*) and archaeella can be found at a single cell pole, both poles or peritrichously around the cell surface.

Functions Other Than Swimming

While the archaeellum is the sole motility apparatus reported in archaea, archaeella are not necessarily limited to providing motility. In several species, archaeella have additional functions. In *Mc. maripaludis*, *P. furiosus* and *Mcc. villosus*, archaeella are known to establish cell to cell contacts and help in the adhesion of the cells to abiotic surfaces (Fig. 2(a)) although this is not a role for archaeella in *Hfx. volcanii*. In the case of *Mc. maripaludis*, both type IV pili and archaeella are needed for surface attachment. Archaeella are also known to play a role in biofilm formation. In the case of *S. acidocaldarius*, the archaeellum is needed at the late stages of biofilm formation for cells to leave the mature biofilm.

Structure and Rotation

Archaeella are typically thinner than flagella, usually 10–14 nm in diameter, although there are rare reports of much thicker archaeella, as in the case of *Haloarcula marismortui* where archaeella can reach 20–22 nm in diameter. Typically, archaeella are many cell lengths long. While flagella have a conserved curved hook region and complicated basal body composed of a series of stacked rings around a rod substructure, archaeella structure is much simpler. The presence of a curved hook-like region is variable, reported for some species like *Mc. maripaludis*, *Mc. voltae* and *Hbt. salinarum*, but absent in *Sulfolobales* and *Hfx. volcanii*. No evidence for a flagellum-like basal body is present in archaeella, although knob-like structures have been reported in some species at the cell proximal end (Fig. 2(b)). In the limited number of cases where it has been determined, archaeella exhibit a right-handed helicity. Like flagella, archaeella are

rotating organelles that can switch the direction of rotation. However, the rotation of archaella is driven by ATP hydrolysis and not ion gradients as in flagella. Recent elegant biophysical studies determined that in the case of *Hbt. salinarum*, the archaella motor torque was estimated to be 50 pN nm and the motor efficiency to be 6%–10%. Remarkably, tethered cells were observed to pause during rotation, which may be the moments when FlaI hydrolyzes ATP to power rotation. The maximum swimming speeds for many well-studied archaea have been reported with a large range from 10 $\mu\text{m/s}$ for *Hbt. salinarum* to near 600 $\mu\text{m/s}$ for *Methanocaldococcus* species. In terms of body lengths per second, these hyperthermophilic methanogens are the fastest organisms on Earth. These extremely fast swimming speeds may be necessary for survival in their hydrothermal vent habitats. Importantly, unlike flagella, archaella do not possess a central channel that would allow subunits to travel through to the distal end to incorporate.

Archaella usually contain multiple archaellins, sometimes one or more major archaellins that dominate the structure, and additional minor archaellins that comprise a much smaller proportion of the structure. However, at the other extreme, certain crenarchaea like *Sulfolobus sp* have fully functional archaella with only a single archaellin gene present. In the case of *Haloarcula marismortui*, the major archaellin that forms the filament can vary depending on growth conditions, leading to the designation of the different archaellins as ecoparalogs.

Archaellum Genes

Almost all of the genes required for archaellum structure and function reside in a single cluster called the *fla* operon. The *fla* operon is best studied in the crenarchaeon *Sulfolobus acidocaldarius* and the euryarchaeon *Mc. maripaludis* (Fig. 3). *S. acidocaldarius* contains a minimum set of only 7 genes, a single archaellin and the *fla* accessory genes *flaX*, *flaF*, *flaG*, *flaH*, *flaI* and *flaJ*. In euryarchaeotes, the *fla* operon begins with multiple archaellin genes (*Mc. maripaludis* has 3; *flaB1*, *flaB2* and *flaB3*) followed by *flaC*, *flaD*, *flaE*, *flaF*, *flaG*, *flaH*, *flaI* and *flaJ*. FlaX is not found in euryarchaeotes (or Nanoarchaeotes or Thaumarchaeotes) while *flaC/D/E* are not found in crenarchaeotes. In some species *flaC*, *flaD* and *flaE* are not distinct ORFs but fused to form *flaCD*, *flaDE* or *flaCDE*. Deletion of any *fla* operon gene, other than some of the multiple archaellin genes in some archaea, leads to nonarchaellated cells. One key gene required for archaellum formation that is typically not found as part of the *fla* operon encodes the pre-archaellin peptidase, called FlaK in methanogens and PibD in other archaea, like *Sulfolobus sp* and *Hfx. volcanii*, an enzyme that removes the signal peptide from archaellins. Signal peptide cleavage is a necessary step in the assembly of the archaellins into the archaellum filament as mutants deleted for *flaK* are nonarchaellated. FlaK/PibD are members of the same family of unusual aspartic acid proteases as the prepilin peptidases that remove signal peptides from type IV pilins, although the archaeal enzymes do not methylate the resulting N-terminal amino acid as found for the bacterial enzymes. Site-directed mutagenesis studies have demonstrated that the pre-archaellin peptidases possess two aspartic acid residues that are critical for enzymatic activity. FlaK seems to have a substrate range limited to archaellins while PibD processes all substrates possessing type III signal peptides, including type IV pilins and bindosome (sugar binding proteins) components. FlaK from *Mc. maripaludis* was the first member of this aspartic acid protease family to be crystallized and its structure was determined at 3.6 Å.

Fig. 3 Archaella operons from a typical crenarchaeote *S. acidocaldarius* and a typical euryarchaeote *Mc. maripaludis*.

Regulation and Regulation Crosstalk

Depending on the archaeon, production of archaella may not be constitutive but can be dependent on the availability of certain nutrients, growth phase and temperature. Molecular dissection of the regulation is available for only a very limited number of archaea, mainly *S. acidocaldarius* and *Mc. maripaludis*. In the latter organism, a transcriptional regulator EarA was shown to be essential for transcription of the *fla* operon and mutants deleted for *earA* were nonarchaellated. In *S. acidocaldarius*, a much more complicated archaeum regulatory network, has been unveiled including phosphorylation-dependent repressors and activators controlled by different kinases and phosphatases. Interestingly, there is crosstalk in the regulation of archaella and adhesive pili in *S. acidocaldarius* as deletion of genes encoding the adhesive pili lead to hyperarchaellated cells. Cross regulation of pili and archaella synthesis also occurs in *Hfx. volcanii*, where pilins are important regulators of archaella-mediated motility. Such crosstalk presumably allows for the production of only one type of organelle depending on whether the conditions call for adherence or motility.

Importance of N-Linked Glycosylation for Archaellation and Motility

Besides genes encoding the Fla proteins, *agl* genes involved in the biosynthesis and assembly of glycans that are N-linked to various cell surface proteins including S-layer proteins, pilins and archaellins have been shown to be important or essential for archaellation and motility. Until recently, only N-linked glycosylation was identified on archaellins but a recent study of archaellins of *Methanospirillum hungatei* identified both O- and N-linked glycosylation. The critical importance of N-glycosylation was demonstrated by the deletion of *aglB* (encoding the oligosaccharyltransferase), the signature enzyme of the N-linked glycosylation pathway, which catalyzes the transfer of the assembled glycan from its lipid carrier to the target protein. Mutants deleted for *aglB* possess archaellins completely devoid of N-linked glycans and these cells are nonarchaellated in *Mc. maripaludis* and *Hfx. volcanii*. Deletion of other *agl* genes lead to mutants able to make and transfer only a truncated glycan. Depending on the severity of the truncation, these mutants may be nonarchaellated or archaellated but with motility defects. Direct evidence for the importance of N-glycosylation of archaellins for assembly of archaella and motility was sought by genetically removing N-glycosylation sites on archaellins in *Mc. maripaludis*, *Hfx. volcanii* and *S. acidocaldarius*. Interesting, three different results were obtained. In *S. acidocaldarius*, all archaellin N-glycosylation sites could be removed with little effect on motility while in *Hfx. volcanii*, removal of even one glycosylation site resulted in complete loss of motility. For *Mc. maripaludis*, at least a single glycosylation site had to be present for archaellation to occur. Whether the role of glycosylation is for filament stability or whether it plays a role in the assembly mechanism or both is still under investigation. Glycosylation has been reported to play a role in protein stability under harsh conditions.

Biochemical Studies of Fla Proteins

Biochemical studies on targeted archaeal proteins have been initiated in efforts to understand how the various Fla proteins interact within the archaeum motor complex, how the motor works and how the archaeum is inserted into the archaeal cell envelope. Early studies reported the expression and purification of *S. solfataricus* FlaI and confirmed that it is an active ATPase. Later, the crystal structure of *S. acidocaldarius* FlaI showed that it assembles into a hexameric conformation induced by ATP binding. The hexamer adapted a crown-like shape where the tips of the crown were formed by the flexible N-terminus of the FlaI monomers. When the N-terminus of FlaI was removed in *S. acidocaldarius*, the cells were still archaellated but unable to swim, showing that FlaI plays two roles: First, it is required for assembly of the filament and secondly, it is required for rotation of the filament by ATP hydrolysis. Based on the homology to the bacterial type IV pili system, FlaI is expected to interact with FlaJ, an integral membrane protein. However, so far no biochemical data has been reported for any FlaJ homologs as the expression of the full-length version of this protein is very difficult. Depending on the species, FlaJ has 7–13 predicted transmembrane domains and most have 1 or 2 predicted large, cytoplasmic loops. It is thought that these large loops serve as an interaction platform for FlaI to form the heart of the archaeum motor. FlaH, highly conserved in all archaeum operons, has a Walker A motif but a non-canonical Walker B motif. FlaH has been shown to bind nucleotides with high affinities, but it does not actively hydrolyze ATP, as was shown for FlaH from both *Mcc. jannaschii* and *S. acidocaldarius*. In vivo, ATP binding by FlaH is essential for archaeum assembly as the FlaH Walker A and Walker B mutants in *S. acidocaldarius* were unable to assemble an archaeum filament. Both mutant forms of FlaH were also unable to interact with FlaI in vitro. In the case of *Mcc. jannaschii*, the addition of ATP lead to a decrease in the affinity of the wildtype versions of FlaH and FlaI. It was proposed that FlaH is important in the archaeum motor complex to regulate the activity of FlaI during assembly and rotation.

FlaX-like proteins are only found in crenarchaeal archaeum operons. FlaX of *S. acidocaldarius* is a monotopic membrane protein that shows no homology to any known proteins. Only expression of the soluble domain, which contains a coiled-coiled domain, was successful. This truncated protein formed very stable ring-like oligomers with an approximate diameter of 20–30 nm, as analyzed by single particle analysis. In vitro assays showed that FlaH, FlaI and FlaX from *S. acidocaldarius* interact with high affinities and probably form a complex in vivo in the archaeum motor complex with FlaX acting as a scaffold during motor assembly (Fig. 6, right panel). Single particle analysis showed that FlaH formed an inner ring inside the FlaX ring implying

that the *S. acidocaldarius* archaeum motor is organized like this. However, so far, a complex including FlaH, FlaX and FlaI could not be formed. In euryarchaea, FlaX is replaced by FlaC/D/E, but for these proteins no structural or biochemical information is available yet.

All archaeum components discussed so far are localized at the cytoplasmic side of the cytoplasmic membrane. FlaF and FlaG both contain a predicted archaeum domain and a hydrophobic stretch at the N-terminus. It is not clear whether the membrane domain is part of a signal peptide that is cleaved during archaeum assembly or whether this domain anchors the proteins in the membrane. The crystal structure of *S. acidocaldarius* FlaF showed an extended β -sheet-containing archaeum domain which was very similar to the recently solved cryo EM structures of the archaeum domains of *Msp. hungatei* and *P. furiosus* (see below). *S. acidocaldarius* FlaF bound to isolated S-layer proteins confirming that the FlaF archaeum domain is extracellularly localized. FlaG can be modelled on FlaF, therefore it is expected that it also exhibits a β -sheet structure. Consistent with FlaF binding to the envelope protein, it is proposed that FlaF/G anchor the archaeum to the S-layer (acting as the stator), or they might interact with the growing filament itself.

Recent Archaeum Atomic Models

Early structural studies on the archaeum revealed a helical symmetry and the lack of a central channel. More recently, atomic models of the archaeum filament and motor have been published. In the case of *Msp. hungatei*, the filament was shown to be composed of a single archaeum (FlaB3) even though the organism has three *flaB* genes. An atomic model of the archaeum filament was presented at 3.4 Å resolution. Each archaeum monomer has a tadpole shape with two domains: An N-terminal domain that forms a long hydrophobic α -helix and forms the inner core of the filament and a C-terminal domain that forms a hydrophilic β -barrel exposed to the aqueous environment. In the C-terminal domain, posttranslational modifications of FlaB3 were identified: 6 sites of potential O-glycosylation (the first case of O-glycosylation of archaeum reported) and one atypical site of N-linked glycosylation. A further site has an unidentified modification that is unlikely to be glycan. Each archaeum monomer interacts with eight neighboring archaeum presumably contributing greatly to the rigidity and stability of the thin filament.

For *P. furiosus*, the filament was resolved to 4.2 Å. As with *Msp. hungatei*, three archaeum genes are present in *P. furiosus* but the filament was found to be predominantly composed of only one, FlaB0. Like the *Msp. hungatei* filament, that of *P. furiosus* was shown to have a hydrophobic core composed of the archaeum N-terminal α -helices with an outer globular domain of β strands. Each FlaB0 monomer interacts with 6 neighbours. Sites of likely N-glycosylation were detected at consensus N-glycosylation sequons in the surface exposed C-terminal domain of FlaB0. A problem seldom addressed with archaeum is how they emerge through the S-layer that cover most archaeal species. The data presented here showed that the pores of the S layer were not large enough to accommodate passage of the 11 nm archaeum filament but it was hypothesized that removal of a single S-layer subunit would be enough to accommodate the diameter of the filament. Excitingly, this study also was able to visualize the archaeum motor complex in situ using sub-tomogram averaging of densities at the base of the archaeum, allowing the creation of a model of the entire archaeum machinery (Fig. 4). The motor was revealed as a bell-shaped structure extending 19 nm into the cytoplasm. It is narrowest (9.5 nm diameter) at the membrane where it is linked by six protrusions of 3 nm. At the membrane distal end, the diameter widens to 18 nm and it is connected to a cytoplasmic ring of 26 nm. It is believed that FlaI is fully embedded in the cytoplasmic membrane while the bell shaped cytoplasmic extension represents FlaI and FlaH. The cytoplasmic ring is hypothesized to be formed from the poorly understood FlaC and FlaD/E. The archaeum motors are co-localized with a so-called polar cap, a sheet-like cytoplasmic structure which may serve as an anchor for the archaeum (Fig. 5).

Archaeum motors were also visualized in *T. kodakarensis*. Similar to the finding in *P. furiosus*, archaeum in *T. kodakarensis* were found to associate with a large cytoplasmic conical structure which was hypothesized to serve as a massive anchor for the filaments. This conical structure also associates with large arrays of chemoreceptors.

The association of archaeum motors with cytoplasmic structures (polar cap or cytoplasmic cone) in *P. furiosus* and *T. kodakarensis* is reminiscent of cytoplasmic discoid lamellar structures (DLS) that were observed in thin sections of *Hbt. salinarum* under archaeum insertion sites decades ago. Subsequently, isolated archaeum from *Hbt. salinarum* were found attached to structures called polar caps which may be the previously observed DLS. Sub-cytoplasmic membrane structures were prominent as potential archaeum anchoring mechanisms in the earliest archaeum assembly models. Similar polar membrane-like structures were also observed in thin sections of various *Methanococcus* species, suggesting that in the Euryarchaeota, at least, such a cytoplasmic anchoring structure may be widespread.

Chemotaxis System Interactions

Unexpectedly, while the archaeum and the flagellum of bacteria are unrelated, both can interact with a conserved bacterial chemotaxis system to detect attractants and repellents in their environment. Both bacteria and many archaea possess CheY which in its phosphorylated form binds to the switch complex at the base of bacterial flagella causing a change in rotation, but archaea lack a discernible homologue of this bacterial switch protein. To integrate the bacterial chemotaxis system with the archaeum, a number of archaea-specific Che and Fla proteins may be involved. FlaX proteins are only found in crenarchaeotes which lack *che* genes. In other phyla like the Euryarchaeota, FlaX is replaced by what are believed to be the functional equivalents FlaC/D/E that appear to facilitate interaction with the chemotaxis system. An archaeal-specific Che protein called CheF is thought to directly

interact with CheY and the CheF-CheY complex is believed to interact with the FlaC/D/E at the archaeum motor to change the direction of rotation. There are several examples of archaea sensing environmental changes and adapting their swimming. For example, certain hydrogenotrophic methanogens have been shown to upregulate the *fla* operon upon H₂ depletion, *Hbt. salinarum* cells switch rotation of their archaeella upon unfavorable UV-blue light stimulus and *S. acidocaldarius* induces swimming under nutrient starvation. Unexpectedly, however, there are examples of archaeellated members of the archaea, such as *Sulfolobus* sp and *Mcc. jannaschii*, that can detect temperature changes and nutrient levels but which lack *che* genes. How this is done is currently unknown.

Assembly Model

Recent data has identified the location and possible functions of most of the Fla proteins within the archaeum, including interaction partners (Fig. 6). Given the simplicity of the archaeum structure vis-à-vis the bacterial flagellum, these studies have provided remarkable progress in the current understanding of the structure and assembly of the archaeum in the past few years, although much is yet to be learned about the order of assembly of the component proteins. The archaeum structure may be considered as composed of two major substructures: The filament and the motor. Since FlaJ and FlaI at minimum are needed to incorporate new archaeellins into a filament, these two proteins at least seem to be the initial ones to start the assembly process, although it is possible the entire motor is assembled prior to archaeellin incorporation. In the *S. acidocaldarius* system, it is believed that FlaJ assembles in the membrane after which FlaI comes into the complex. FlaH will then bind to FlaI, which will initiate the ring formation of FlaX around the motor complex. This is based on the result that in the FlaH deletion mutant the FlaX protein was degraded. In phyla other than Crenarchaea, the FlaC/D/E take the place of FlaX.

With at least FlaJ and FlaI in position, the formation of the filament can occur. Archaeellins are made as preproteins and transported, perhaps with the aid of chaperones, to the cytoplasmic membrane. Here two posttranslational events must occur; the signal peptide must be cleaved through the actions of the pre-archaeellin peptidase FlaK/PibD and the archaeellins typically are modified with N-linked glycans through the activity of AglB. The order of the two events is unknown but each can occur in the absence of the other, as shown in studies in *Mc. maripaludis* using strains deleted for either *flaK* or *aglB*. The final step involves the incorporation of the modified archaeellins into the base of the structure by the ATP-hydrolyzing activity of FlaI.

The stage at which FlaF/FlaG, the possible stators, are assembled during this process is not known and how the archaeella interact with the proposed cytoplasmic anchoring structure, the polar cap, is likewise completely unknown.

Fig. 6 Current models of euryarchaeal (*Mc. maripaludis*) and crenarchaeal (*S. acidocaldarius*) archaeum structures, showing location of known Fla proteins as well as processing steps (signal peptide removal and N-linked glycosylation) for the archaeellins prior to their incorporation into the filament. Glycan structures are not shown on the assembled archaeellins for clarity. CM, cytoplasmic membrane; AglB, oligosaccharyltransferase that transfers glycan from lipid carrier to select asparagine residues in target proteins, including archaeellins; FlaK/PibD, pre-archaeellin peptidase that remove the signal peptides from archaeellins.

Future Outlook

It is clear that the archaeum is a remarkable motility apparatus. With a complexity far less than that seen in bacterial flagella, it nevertheless is an extremely stable and efficient rotating organelle that can impart swimming speeds that far exceed that observed for even the fastest bacteria. Despite its apparent simple protein composition and significant strides made in the biochemical analysis of its component proteins, much remains to be discovered about how and in what order the apparatus is assembled, how it is stabilized in the unusual archaeal envelope (vis a vis potential stators and cytoplasmic anchoring devices), how it interacts with the chemotaxis apparatus to alter its rotation and how its regulation is interconnected with the control of genes involved in adhesion and biofilm formation that allow the cells to best adapt to their changing environments. Even though there are only few data available on different archaea proteins and in situ archaeum complexes, it is clear that, similar to the bacterial flagellum, this archaeal molecular device has been adapted differently in different archaeal phyla. It is important to get structural data of many more archaea complexes to be able to compare these different structures.

ROS	Reactive oxygen species

Defining Statement

In this article, different aspects of ongoing work in the genus *Aspergillus* are discussed, ranging from toxin production, pathogenicity to humans and animals, traditional and modern biotechnological uses, genomics, and the use of *Aspergillus nidulans* as a model organism to study fundamental problems of cell and molecular biology.

Note

For *Aspergillus* genes and proteins, the standard nomenclature is followed, for example, the *benA* gene encodes the BenA protein, which is a β -tubulin. When genes or proteins of other species are mentioned, the standard nomenclature for each species is used.

What is *Aspergillus*?

An *Aspergillum* is an instrument used in the Roman Catholic mass to sprinkle holy water over the heads of the faithful. *Aspergillus* is a genus of the ascomycete fungi (see below). In 1729, Pietro Antonio Micheli, priest and botanist, described the asexual spore heads (conidiophores; see below) of a number of common molds. The heads of some of these molds showed rows of spores radiating from a globular central structure, which he thought resembled the *Aspergillum* he was familiar with. The morphology of the conidiophore is still an essential taxonomic marker. Fig. 1 compares the original Micheli's drawing with modern observations of conidiophores.

The classification of the kingdom fungi into major groups (Phyla, such as Ascomycota and Basidiomycota) is based on the morphology of the sexual reproductive structures. The Aspergilli should be placed among the ascomycetes (see below), those fungi that have the products of meiosis placed in a sac or ascus. However, most of the fungi we call Aspergilli (see below) do not have sexual reproduction, and thus no asci. To solve this problem, mycologists created the group fungi imperfecti or otherwise called deuteromycetes in which they placed all fungi without known sexual reproduction. This is a mixed bag without any phylogenetic significance. This provokes ridiculous situations, by which a fungus would change genus, and in fact phylum, every time sexual reproduction is detected. Thus the 'imperfect' fungus *Aspergillus nidulans* (see below) becomes the 'perfect' fungus *Emericella nidulans*, and it is placed in a different phylum from *Aspergillus sydowii*, in spite of the fact that morphological and molecular data show the two organisms to be close relatives. Names like *Emericella*, *Eurotium*, and *Neosartorya* design Aspergilli with a sexual cycle (also called teleomorphs). Thus, *E. nidulans* is the teleomorph (perfect form) of *A. nidulans* (anamorph, imperfect form). No one but a mycologist would know that we are talking about one and same organism.

This situation exists for many other genera. The only solution to this conundrum is to completely abandon the division 'fungi imperfecti' and choose in each case one and only one name for a given genus. As early as in 1926, Thom and Church, Thom and Raper (1945), and Raper and Fenell (1973) proposed that "the generic name *Aspergillus* should be applied to all these fungi whether or not an ascospore (sexual) stage was produced". The main morphological characteristics of the genus, drastically abbreviated from Raper and Fenell (1973), are "vegetative mycelium consisting of septate branching hyphae ... Conidial apparatus developed as conidiophores ... conidiophores ... broadening into turbinate elliptical, hemispherical, or globose fertile vesicles ... bearing fertile cell or sterigmata ... conidia (asexual spores) ... produced successively from the sterigmata. Ascocarps (asci, containing

[☆]Change History: April 2019. Claudio Scazzocchio has made minor changes to the reference and text.

This article is an update of C. Scazzocchio, *Aspergillus: A Multifaceted Genus*, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 401–421.

Fig. 1 The left panel shows a scan of copper-engraving 91 from Micheli's *Nova plantarum genera*, showing his drawings of *Aspergillus* conidiophores. The description in Micheli's text suggest that figure of the engraving, called *Aspergillus capitatus* (*muffa turchina*, blue mold) by Micheli, may correspond to *Aspergillus fumigatus* or a close relative. The right panel shows on the top a scanning electron micrograph of the conidiophore of *Aspergillus nidulans* and at the bottom an epifluorescence micrograph. The preparation is stained with DAPI which reveals the nuclei of the conidia and of the subjugent structures of the conidiophore. Both pictures on the right panel have kindly provided by Reinhard Fischer. Reproduced with permission from Kues, U., Fischer., R. (Eds.), 2006. *The Micota I, Growth Differentiation and Sexuality*. Berlin: Springer-Verlag. Micheli describes in his text the conidiophore as been formed by a stalk, and a head, which he called 'placenta' carrying the conidia. See legend to Fig. 13 for the correspondence with the modern terminology.

sexual spores) found in certain groups only, unknown in most species". Recent work shows that the Aspergilli are as a whole a monophyletic group, where loss of sexual reproduction has occurred many times independently.

Not everyone agrees with the reasonable proposal of Raper and Fenell. A recent classification (2005) of the ascomycetes places the *Aspergillus*-related teleomorph genus names in the kingdom Fungi, subphylum Pezizomycotina, class Pezizomycetes, family Trichocomaceae. The genera *Aspergillus* and the related *Penicillium* do not appear in this list as they are considered imperfect forms! Throughout this article, the generic name *Aspergillus* is used, as a genus comprising all the related 'teleomorphs' together with the forms where sexual reproduction is absent. The teleomorph name is also indicated when appropriate, as this is used in some important databases (as NCBI). The kiss of death to the concept of 'fungi imperfecti' was delivered by recent molecular data that show that the genomes of 'imperfect' Aspergilli, include the genes that determine mating types, these genes being clearly homologous to, and even placed in the same place in the chromosome as, the ones found in the 'perfect forms' ("*The Genus Aspergillus in the Genomic Era*").

Fungi of the genus *Aspergillus*, which includes about 200 species, are important in public health as toxin-producing food contaminants, as human and animal pathogens, as useful fungi in traditional and modern biotechnological processes, and finally one species has been used as a model to study a number of cellular processes. A recent development is the availability of eight complete genomes within the genus, a matter of obvious practical, taxonomical, and evolutionary importance.

Food Contamination by Aspergilli

Many organisms, including bacteria, fungi, and plants, produce secondary metabolites. These are molecules that can be very complex and are not obviously necessary for the viability of the organism. In fungi, they are produced during the stationary phase and their synthesis is usually coordinated with asexual sporulation (see below). Some secondary metabolites are extremely toxic, and when fungi grow on stored foods, they secrete them, provoking food spoilage and eventually intoxications that may be fatal. Among the Aspergilli, the two main culprits are strains of *Aspergillus flavus* and *Aspergillus parasiticus*, which secrete aflatoxins, a group of highly substituted coumarins. Strains that are closely related may vary drastically in their ability to produce the toxin. These saprophytic fungi can grow on a variety of foodstuffs, or even on plants before harvesting. In fact, *A. flavus* can be considered a weak opportunistic, nonspecific plant pathogen. The aflatoxins were discovered in 1960 when thousands of turkeys died in an English hatchery. The contaminated food was a ground peanut meal. The most serious contamination is that of maize. While this contamination results in loss of hundreds of million dollars every year to farmers in developed countries, the impact on human health is extremely serious in developing countries. Of the related compounds called aflatoxins, Aflatoxin B1 is one of the most toxic and carcinogenic compounds

known, as judged by tests on laboratory animals. Maize stored under warm and humid conditions becomes contaminated with aflatoxigenic *Aspergilli*, and when consumed by humans or animals, this can lead to liver failure and death. Periodic outbreaks of acute aflatoxin poisoning occurred in East Africa, the latest in 2004, leading to 125 deaths. It is more difficult to assess the damage caused by chronic aflatoxin poisoning and the correlation of the toxin in food with the frequency of liver cancer. Controls on aflatoxin levels are tight in developed countries; they are, however, impossible to be enforced in developing countries, where people would store grains in their homes and the stored grain may be the only available food. Human aflatoxicosis is a disease of poverty.

The *Aspergilli* can contaminate food with other toxic molecules. Only the ochratoxins, produced by a number of *Aspergilli* and *Penicillia* will be discussed below. The ochratoxins comprise an isocoumarin moiety and a phenylalanine ring joined by an amide bond. Ochratoxin contamination has been reported in many foodstuffs, including grapes, nuts, cacao, coffee beans, and spices. In poultry, and laboratory animals, ochratoxins provoke serious kidney lesions. It is difficult to assess damage to human health caused by chronic exposure to ochratoxins. They have been implicated as a cause of testicular cancer. The similarity of symptoms of porcine mycotoxin nephropathy with that of Balkan endemic nephropathy, a disease localized to regions of Bulgaria, Romania, and former Yugoslavia, has implicated ochratoxins as causal agents of the disease. A similar case can be made for chronic interstitial nephropathy of northern Africa. A case of acute renal failure, almost certainly due to the exposure to an ochratoxin, has revived the hypothesis that exposure to this mycotoxin is the cause of the 'mummy curse', which is alleged to have killed archaeologists who have braved the prohibition to open royal tombs.

Aspergillus as Pathogens

The common fungus diseases are mild and superficial, while those that are deep-seated and endanger life are so rare that one man can seldom see enough cases to make any extensive study of them. (Henrici, Presidential Address to the Society of American Bacteriologists, 1939).

Aspergillus as Human Pathogens

The emergence of species of the genus *Aspergillus* as, in many cases, intractable human pathogens, has gone hand in hand with the progress of medicine. All *Aspergilli* encountered as causal agents of human or animal diseases are opportunistic pathogens. The *Aspergilli* are all saprophytes, usually growing in decomposing vegetal material. The main pathogen, *Aspergillus fumigatus*, thrives on compost.

Before the transplant era, *Aspergillus* infections were only encountered sporadically. Farmer's lung is a general name for an allergic disease that could be due to different causal agents, bacteria or fungi, of which the *Aspergilli* are the main culprits. It is an occupational disease associated with high exposure of spores, in environments such as grain silos. In the nineteenth century, two exotic occupational diseases associated with *A. fumigatus* were described: the *maladie de gaveurs de pigeons* and the *maladie de peigneurs de cheveux*. These pulmonary diseases were associated with people who force-fed pigeons and with people who sorted hair for wigs, respectively. A perusal of the Pathogenesis article by Austwick, included in Raper and Fennell's monograph of 1973, leaves the impression that a large number of *Aspergillus* species could be opportunistic pathogens, that pulmonary disease was basically an occupational hazard, that virtually every organ could be colonized by one or other *Aspergillus* species, and that once the fungus was established the prognosis was bleak. Henrici, compared invasive fungal diseases to autocatalytic processes, sluggish to start, but eventually becoming unstoppable. The comparison still holds today, except that immunodepression gives the fungus a head start. *A. fumigatus*, was then as now, the prevalent species, followed by *A. flavus*.

Three types of respiratory pathologies are associated with the *Aspergilli*. Exposure to the fungus can result in allergic diseases, such as farmer's lung and allergic bronchopulmonary aspergillosis, encountered mainly in asthmatic and cystic fibrosis patients. *Aspergillus* spores can germinate in preexisting cavities such as the sinuses or those present in the lung as a result of tuberculosis. This leads to localized Aspergillomas in immunocompetent subjects, which can be treated surgically and/or with appropriate drugs. Finally, the most threatening form is the invasive Aspergillosis, associated, in most but not in every case, with a depression of the immune system.

The ability to perform grafts of bone marrow cells in leukemic patients, of solid organs such as kidney, liver, and lung, has been accompanied by the emergence of invasive Aspergillosis. AIDS patients are also at risk, but *Aspergillus* spp. are encountered less frequently in these patients than *Pneumocystis carinii*, *Candida* spp., or *Cryptococcus neoformans*. Susceptible patients include those affected by neutropenia. Neutropenia can result from leukemia or from the chemotherapy used to control it, or be subsequent to treatment with immunosuppressant used in bone marrow, stem cell, or organ transplants. Patients of systemic diseases treated with immunodepressing drugs, mainly corticosteroids, are also at danger. In all these patients, germination of *Aspergillus* spores leads to invasive aspergillosis, usually of the lung, which breaking through the blood vessels can infect other organs. There seems to be no organ in which the fungus cannot grow in the absence of an appropriate immune response. In almost all cases, spores enter through the respiratory tract and germinate in the parenchyma of the lung, leading to invasion of the bronchiolar walls and the adjacent blood vessels. Invasive Aspergillosis has been classified into angioinvasive and bronchio-invasive forms, but this classification is somewhat artificial, as invasion of both bronchioles and arterioles can be seen in the same patient. This leads eventually to respiratory failure and death. Fig. 2 shows an *Aspergillus* mycelium grown in lung tissue.

Fig. 2 A neutropenic mouse lung tissue, experimentally infected with *Aspergillus nidulans* is shown at 20 h postinfection. The fixed sections were stained with Grocott's Methenamine Silver. The pictures show hyphae (stained brown) actively growing in the lung tissue (stained green). Photograph kindly provided by Elaine Bignell.

A very recent review estimates an eight-fold increase in *Aspergillus*-disseminated infections, from the 1970s to the present day. Between 9% and 17% of all deaths in transplant recipients are due to *Aspergillus* infections according to recent data. The prognosis of invasive aspergillosis is grim; mortality in transplant patients infected with *Aspergillus* sp. is never lower than 60% for patients treated with antifungals and 100% in nontreated patients.

The most common encountered species in all *Aspergillus*-related pathologies is *A. fumigatus*, *A. flavus*, *Aspergillus niger*, *A. nidulans*, and *Aspergillus ustus* have also been recorded. One recent study of nosocomial infection reports that of 458 patients 154 were infected with *A. fumigatus* and 101 with *A. flavus*. The same and other studies establish a link between construction or renovation work in the vicinity of the hospital and frequency of invasive aspergillosis and conclude that even very low spore counts (1 spore per m³) are dangerous to immunocompromised patients. Genotyping has shown that there are no specific pathogenic strains and suggests that every *A. fumigatus* strain present in the environment is a potential risk for immunodepressed patients. Recently, an upsurge of *Aspergillus terreus* infections has been observed. This is particularly worrying, as the organism is resistant to Amphotericin B, the drug most widely used to treat invasive Aspergillosis. The prevalence of *A. fumigatus* infection has not been explained. We are all continuously exposed to fungal spores and two obvious factors can be considered to explain the prevalence of one or other species. The first is the spore density in specific environments. Unfortunately, many early studies simply report the density of '*Aspergillus*' without any further species discrimination, let alone genotyping. It is generally accepted that the high frequency of *A. fumigatus* infections cannot be explained by a prevalence of the organism in the environment. The second parameter to be considered is spore size. The smaller the spores, the most likely they are to reach the alveolar tissue of the lung, as they will be less susceptible to removal by the mucociliary tissue of the respiratory tract. *A. fumigatus* spores are usually about 2–3 µm in diameter, at the lower end of the genus. Specific gravity of spores has, to my knowledge, never been measured. Another obvious parameter is thermotolerance, especially in relation to spore germination. However, it is unlikely that the combination of small spores and ability to germinate rapidly at 37°C be sufficient to explain the prevalence of *A. fumigatus*. Both characteristics are shared by *A. fumigatus* and *A. nidulans*, the latter being rarely encountered as an opportunistic pathogen. Another possibly interesting parameter is spore hydrophobicity. This is determined by a family of proteins called hydrophobins. Strains of *A. fumigatus* lacking a specific hydrophobin become more sensitive to macrophage killing. Sensitivity of different species to neutrophil and macrophage killing has been sporadically, but not systematically, assessed.

It is important to distinguish putative specific virulence determinants from essential metabolic processes, even if the latter can be potential drug targets. Only those processes, that when blocked, by mutation or otherwise result in reduced virulence but do not affect the growth of the fungus outside infected tissues, can be considered proper virulence determinants. This is of course conditional to the media in which the fungus is tested, my feeling is that the more we know about the metabolism of the fungus in the wild, the less we will be inclined to call a specific metabolic step a 'virulence determinant'. It is not surprising that engineered strains, deficient in essential biosynthetic pathways, or cell wall biosynthesis show reduced or no virulence. As an example, strains blocked in lysine biosynthesis show reduced virulence, but this tells nothing about virulence, it reveals that lysine is limiting in the alveolar environment. However, as some of these processes are fungal-specific, they are potential targets for antifungal drugs.

Secondary metabolites and nonribosomal peptides vary considerably from one fungal species to the other, and thus they represent an interesting avenue of research bearing on virulence. These metabolites may have evolved in saprophytic organisms in response to the presence of competing organisms in a common environment. As such, they may be cytotoxic and eventually

involved in pathogenicity. One of these metabolites, gliotoxin, a substituted diketopiperazine, has received considerable attention. It has been implicated in the suppression of the innate immune response, including apoptosis of neutrophils. However, specific inability to synthesize gliotoxin does not affect the virulence of *A. fumigatus* in the neutropenic mouse model. However, deletion of *laeA*, a gene necessary for the transcription of a large number of genes encoding enzymes of secondary metabolite synthesis (see 'Medically useful secondary metabolites' and 'Regulation of secondary metabolism'), including gliotoxin, does affect the virulence of *A. fumigatus*. Absence of *LaeA* leads to a pleiotropic phenotype, and the decreased virulence may result from a combination of factors. It seems that at present we simply do not know why *A. fumigatus* is the prevalent pathogen and why other Aspergilli are occasional pathogens. It is likely that a complex combination of characters is responsible for triggering the autocatalytic process proposed by Henrici. Opportunistic pathogens have not evolved as such, in a coevolutionary relationship with a host organism, it thus may be completely fortuitous that one or other of them be able to thrive in the tissues of immunocompromised patients.

It is important to determine which are the barriers that prevent fungal infections in immunocompetent subjects. Alveolar macrophage would get rid of ungerminated conidia, while polymorphonuclear neutrophils destroy hyphae mainly through the action of reactive oxygen species (ROS). One proposed mechanism involves the recognition of fungal cell wall constituents, such as β 1-3-glucans, by macrophage membrane receptors, leading to phagocytosis. Recent studies, however, imply a less clear-cut distribution of labor, with neutrophils also having an important role in preventing conidial germination, which correlates with the susceptibility of neutropenic patients. Dendritic cells are able to ingest *Aspergillus* spores, thus being able to present specific antigens to T cells, a role shared with macrophage. Both CD4⁺ T and CD8⁺ T cells respond to fungal antigens, CD4⁺ T cells produce cytokines, which further recruit neutrophils. The protective role of specific antibodies is subject to discussion, as they are found in infected patients, which they fail to protect. Recently, protective roles have been postulated for surfactants secreted by epithelial cells that interact with conidia and may facilitate phagocytosis. A crucial role in innate immunity to opportunistic fungi is carried out by PTX3, a protein belonging to the pentraxin family of secreted, soluble proteins. PTX3 is essential in conidial recognition by macrophage and dendritic cells, and homozygous knocked-out mice genes are highly susceptible to experimental infection. The study of the immune response to infection by *Aspergillus* spores has made considerable progress in recent years and may lead to treatments, which promote the recovery of the immune response of the patient as an alternative or in association with antifungal drugs.

Fungi are eukaryotes, more closely related to metazoans than to plants, that is why ascomycetes such as *Saccharomyces cerevisiae* and *A. nidulans* are useful models in molecular and cell biology. Many cell processes are common to the fungal and the animal cell, and that, in order to find effective antifungal agents, is necessary to identify those processes that will inhibit growth of the fungal cell without damaging the host. Flucytosine (5-fluorocytosine) has been used as an antimycotic since 1968. In clinical practice, it is used mainly in candidiasis. It affects nucleic acid synthesis and thus can hardly be considered a specific antifungal agent. Four other classes of compounds are currently used to treat fungal infections in clinical practice. The polyenes, such as Amphotericin B, interact directly with ergosterol in the fungal cell membranes leading to leakage of potassium ions and cell death. Amphotericin B, one of the most used antifungals, interacts with animal cell membranes also, which can lead to acute kidney failure. The azoles, such as fluconazole or the newly developed voriconazole, inhibit specifically lanosterol demethylase, blocking the synthesis of ergosterol. They are less toxic than Amphotericin B, and a case has been made to use voriconazole as a first line, rather than a second line, drug for the treatment of invasive Aspergillosis. However, they are not free of secondary effects. The allylamines such as Terbinafine also result in ergosterol depletion by inhibiting squalene epoxidase. Finally, the echinocandins are really specific antifungal drugs, as they affect the fungal-specific process, the synthesis of the glucans of the fungal cell wall by inhibiting noncompetitively β -1,3-glucan synthase. Better knowledge of fungal development and metabolism, the search for genes essential for the pathogen, but absent in, or not essential for the host should lead to the development of new specific antifungal drugs. A different and complementary approach is to reinforce the immunological response of the host. This includes the possible development of an antifungal vaccine. Besides the uncertainty as to whether protective antibodies can be produced, the large variety of fungi that can affect immunodepressed patients posits an additional difficulty. Recently, a whole roster of new fungi appeared as opportunistic pathogens, such as *Fusarium*, black molds, and zygomycetes. Success against *Candida* has been followed by an increase of *Aspergillus* infections. Preventive treatment with voriconazole, effective against *Aspergillus*, has been followed by infections by a whole variety of zygomycetes. It has been proposed that a vaccine using β -1,3-glucan as antigen, which is a universal component of fungal cell walls, may be worth exploring. An early diagnosis is essential in the successful treatment of invasive fungal infections. Immunological detection of cell wall components such as galactomannan and 1-3- β -D-glucan and detection of fungal DNA by PCR are being developed and evaluated.

***Aspergillus* in Veterinary Medicine**

Aspergilli are encountered, even if uncommonly, in veterinary practice. Here, as in the human disease, *A. fumigatus* is the most frequently encountered pathogen, followed by *A. flavus*. In mammals, canine sinonasal Aspergillosis, guttural pouch mycosis of horses, and bovine mycotic abortion are the most common diseases, but infection of other species and pulmonary and generalized aspergillosis has also been described. The horse disease is correlated with the presence of an extension of the Eustachian tube, the guttural pouch, an organ of uncertain physiological significance exclusive of horses, other Equidae, and rhinos and tapirs. This organ could provide temperature and humidity conditions suitable for the growth of *Aspergillus*. Bovine mycotic abortion is correlated with

confinement to sheds, which leads to exposure to high concentrations of spores. More surprising is the finding of pulmonary Aspergillosis in free-range dolphins. If the finding of *Aspergillus* infections in mammals is sporadic and infrequent, birds are at a much higher risk. The main pathogen is *A. fumigatus* and the route of entry is the respiratory tract. In a large postmortem study, 4% of more than 10,000 birds showed fungal infection of the respiratory tract, probably in most cases due to *A. fumigatus*. Aspergillosis affects both free-ranging and domestic birds. Turkeys, poultry, and waterfowl are commonly affected but fatal infections of penguins, ostriches, and rheas have also been reported. The susceptibility of birds to Aspergilli has been explained by both anatomical characteristics of the respiratory system and cellular differences related to innate immunity such as the absence of alveolar macrophage.

A. sydowii, a Specific Pathogen for Gorgonian Corals

An ecologically menacing new Aspergillosis affects Gorgonian (fan) corals, mainly but not exclusively *Gorgonia ventalina* (infections of *Gorgonia flabellum* and one outbreak affecting *Pseudopterogorgia americana* have been reported). Up to the present time, it has been recorded only in the Caribbean Sea, first identified in Saba in 1996 and studied intensively in the Florida Keys. In an epizootic starting in 1997, more than 50% of the sea fan corals were lost. A subsidence of the epizootic has been since reported. The organism responsible is exclusively *A. sydowii*. The restricted host–pathogen specificity contrasts with the situation described above for mammals and birds. This species is a common saprophyte, which can be isolated from a number of environments. Cultures isolated from diseased *G. ventalina* are infectious, while strains isolated from nonmarine environments are not. As only three and two strains respectively were analyzed, this experiment is not definitive. The pathogenic and nonpathogenic strains do not form separate clades when molecular markers are analyzed. As *A. sydowii* does not sporulate in seawater, aerial dissemination has been suspected. One hypothesis is that the spores are carried by dust storms, originating in the North Africa. While fungal spores are surely carried by dust storms, no genotyping work confirming this hypothesis has been reported. Warming and nutrient effluents, including nitrates, have also been blamed for the outbreak. Obviously, these possible causes are nonexclusive. It is possible that the decrease of the epizootic is due to selection for resistant strains of *G. ventalina*. Thus, sea fan infection by *A. sydowii*, besides being an ecological menace, provides an interesting opportunity to study a specific host–parasite interaction involving an *Aspergillus*, and the elucidation of the mechanism of resistance could lead to the discovery of new antifungal compounds, for which there is a crying need. An infected sea fan coral is shown in Fig. 3.

Fig. 3 A specimen of the fan coral *Gorgonia ventalina* infected with *Aspergillus sydowii*. The infected areas are deep purple. The purple gall-like growths may be a result of the infection. A necrotic area surrounded by a deep-purple ring can be seen at the bottom left of the colony. Bar 5 cm. The photograph has been kindly provided by Kiho Kim.

Useful *Aspergilli*

Aspergillus biotechnology ranges from the first steps of sake fermentation to the production of recombinant mammalian proteins. These processes are briefly summarized below.

Oriental Food Uses of *Aspergillus*

The use of *Aspergilli* in the food industry in the far East relies on the extracellular enzymes secreted by the fungus when grown on solid or semisolid substrates. These technologies originated in China more than 2000 years ago. An old review cites more than a hundred such different fungal fermentations. The main products are shoyu (soy sauce), miso (fermented soybean paste), and sake (rice wine). The production of soy sauce involves the fermentation of a mixture of cooked soybeans and wheat. The mixture is inoculated in traditional production by 'koji', which derives from a previous fermentation, or in more modern procedures by a spore suspension of specific strains of *Aspergillus oryzae* or *Aspergillus sojae*. A second fermentation is carried out by lactic acid bacteria and yeasts. In the production of sake, the Japanese wine derived from rice, the steamed rice is inoculated with spores of *A. oryzae*, and the hydrolyzed product is used as the substrate for alcoholic fermentation by *Saccharomyces sake*. The *Aspergillus* strains used in the soy sauce production differ from those used for sake production, the former are selected for high protease, the latter for high amylase titers. Both *A. oryzae* and *A. sojae* belong to the *A. flavus* groups, and genomic analysis has confirmed the very close relationship between *A. oryzae* and *A. flavus*, while *A. sojae* is considered a domesticated strain of *A. parasiticus*. Through the centuries, the organisms have been in use, they have been selected for both high extracellular enzyme titers and nil toxin production, at least under fermentation conditions. *Aspergillus* fermented food products represent, according to a recent source, 2% of the gross national product of Japan.

Extracellular Enzymes Produced by *Aspergilli*: *Aspergilli* as Hosts for Recombinant Proteins

The *Aspergilli* are major producers of enzymes such as carbohydrate hydrolases, lipases, and proteases, used in a variety of industries such as food, beverages, detergent, and animal food additives industries. The first microbial enzyme to be marketed (1894) was an amylase, 'takadiastase', produced from *A. oryzae*. At least 27 different enzymes are produced industrially by the *Aspergilli*. Different species, mainly but not exclusively, of the *A. niger*, *A. oryzae*, and *A. sojae* groups have been optimized for the production of specific enzymes. In some cases, increased production has been achieved through proprietary recombinant procedures, which allows an increase in the copy number of homologous and in a few cases heterologous enzyme genes. Chymosin (rennin) is an enzyme essential for cheese production, which prior to its heterologous production by *A. niger* var. *awamori* (and other microorganisms), had to be extracted from calf's stomach. The stunning efficiency of some of the *Aspergilli* in the process of enzyme secretion ($>20 \text{ g l}^{-1}$), the considerable experience of the fermentation industry, and the fact that many procedures involving *Aspergilli* are generally regarded as safe (GRAS) had suggested that the *Aspergilli* could be used as 'cell factories' for the production of heterologous proteins. This has been successful for some recombinant enzymes (chymosin, lipase, and phytase), but not for high valued, medically important mammalian proteins. Lactoferrin is produced in commercial quantities by recombinant strains of *A. awamori*. More research is needed to understand why some filamentous fungi are so efficient at secreting many fungal proteins but are inefficient as heterologous hosts. Tissue plasminogen activator and interleukin have been experimentally produced at a rate of $12\text{--}25 \text{ mg l}^{-1}$ in a protease-less mutant of *A. niger*. A number of bottlenecks, such as specificity of glycosylation and the onset of the unfolded protein response by the translation of foreign proteins, are under active investigation.

Aspergillus and Production of Organic Acids

Depending on culture conditions, strains of *A. niger* are able to excrete a number of organic acids such as oxalic (used in metal leaching), citric, and itaconic acids and are thus used in their industrial production. Citric acid, a tricarboxylic acid, is an intermediate of the Krebs cycle. It is used in the food, beverage, and pharmaceutical industries. The annual production of citric acid, quoted for 2001, was 1 million tons. The main producing organisms are strains of *A. niger*. Since the ability of the organism to divert its metabolism to the production of citric acid was detected, industrial strains, that can convert over 90% of the carbon source in the culture media (carbohydrates) into citric acid were selected. Industrial carbon sources are low-grade molasses (typically sugar beet), but in principle many other residues of industrial process could be used. Specific culture conditions such as high concentrations of carbon source, low pH, and limitation of ions such as manganese are essential. It is not clear how the metabolism of the organism is diverted to citric acid overproduction. The production of citric acid implies that there is a bottleneck in the Krebs cycle, so that much more citric acid is produced than that is utilized in the cycle. Citrate itself inhibits phosphofructokinase I, the enzyme that catalyzes the conversion of fructose-6-phosphate to fructose-1,6-bisphosphate, a crucial step in glycolysis. It has been proposed that under the culture conditions used, this inhibition is counteracted by other metabolites, thus removing this feedback inhibition of citrate production. Alternatively or additionally, tricarboxylic acid mitochondrial transporters leak out citrate from the mitochondrion, thus depleting the cycle.

Itaconic acid is a dicarboxylic acid, which is used in industry as a precursor of polymers used in plastics, adhesives, and coatings. New uses of itaconic acid-derived polymers are under active investigation. The production of itaconic acid for 2001 was quoted as 15,000 tons. There is a renewed interest in this chemical as industry searches for substitutes of petroleum-derived chemicals. Virtually all itaconic acid produced is by fermentation by specific strains of *A. terreus*. Itaconic acid production is a further perversion of the Krebs cycle, citrate is converted as normally into *cis*-aconitate, which for reasons unknown is, in some organisms, decarboxylated into itaconitate, which has no known metabolic role in the cell.

The fact that different strains of *Aspergillus* and more generally of fungi can divert metabolic pathways to the overproduction and secretion of useful chemicals, coupled with the fact that these organisms can grow on residues of processes such as sugar and ethanol production, open the possibility of engineering pathways to produce high value chemicals through 'green', low polluting, waste-eliminating procedures.

Medically Useful Secondary Metabolites

Of the useful fungal secondary metabolites, the most well-known are the β -lactam antibiotics, penicillin and cephalosporin, and their derivatives. Some *Aspergilli*, such as *A. nidulans*, produce low titers of isopenicillin N. This has been useful in the elucidation of the genomic organization and regulation of the pathway. It has already been mentioned above (see Section "*Aspergillus* as Human Pathogens") that the echinocandins are specific antifungal drugs. Anidulafungin is a semisynthetic derivative of echinocandin B₀, produced by *A. nidulans* var. *echinulatus*. Anidulafungin has been recently introduced in clinical practice and it is specifically indicated to treat *Candida* infections of the digestive tract. The most widely used secondary metabolite produced by an *Aspergillus* is lovastatin, produced by *A. terreus*. This metabolite, as other statins, is used in medical practice to reduce cholesterol levels. The market for statins has been estimated at more than 12 billion US\$ annually. Statins are specific inhibitors of the 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase, which reduces HMG-CoA to mevalonate. Statins are built around a common polyketide skeleton, have a structure similar to HMG, and act as competitive inhibitors of the HMG-CoA reductase. As other secondary metabolites, statins are synthesized by complex sequential steps, involving polyketide synthases, the genes coding for the cognate enzymes map in a 64 kb gene cluster. Gene clustering and its possible role in the synthesis of secondary metabolites is discussed in 'Regulation of secondary metabolism'.

A. (Emericella) nidulans as a Model Organism

The *A. nidulans* Genetic System

In 1953, Guido Pontecorvo published a 97-page review on the 'Genetics of *Aspergillus nidulans*'. Why did Pontecorvo and coworkers spend a considerable amount of time and energy to develop a genetic system for what was then an exotic organism? One of the key problems of biology was, at the time, that of the nature of the gene. The classical image of the gene was that of a discrete element, and mutations were considered to be alternative states of this element. The gene was an abstract concept whose molecular nature was elusive. The image of the gene as an indivisible, discrete unit was based on the experimental fact that mutations that did not complement were not separable in recombination experiments. That is, crosses of individuals carrying different alleles of the same gene, wild-type progeny were never obtained. 'Never' was a few dozen progeny in mice, a few thousands in *Drosophila melanogaster*. The modern reader may not grasp how fundamental the problem was at the time. In the 1940s, there were already exceptions to the 'nonrecombination' rule. In *D. melanogaster*, a few noncomplementing mutations could recombine in crosses to yield rare wild-type individuals. These mutations were called 'pseudo-alleles'. Pontecorvo was looking for a system where hundreds of thousands progeny could be scored. *A. nidulans* happened to be such an organism. By early 1950s, it became clear in Pontecorvo's laboratory, through the work of Alan Roper, followed by Bob Pritchard, that the gene was divisible. The paradigmatic work on the divisibility of the gene was carried out by Seymour Benzer using the bacteriophage T4., "That is, that the gene as a working unit in physiological action is based on a chromosome segment larger than the unit of mutation or recombination" Roper (1953) and "The classical 'gene' which served at once as the unit of recombination, of mutation, and of function, is no longer adequate. These units require separate definition. A lucid discussion of this problem has been given by Pontecorvo" Benzer (1957). The phage system of Benzer was so powerful and elegant that *A. nidulans*, as a system to study the fine structure of the gene, seemed redundant. Nevertheless, a beautiful genetic system was there, ready for the taking. I dare say that in 1953 no system afforded the same degree of sophistication.

This system allows conventional meiotic genetics, carried out by analyzing the progeny contained in a fruiting body (cleistothecium). The cleistothecium may contain as many as 100,000 thousand asci, each containing eight ascospores, the product of a single meiosis and an additional mitosis. In the standard genetic analysis, the products are analyzed 'in bulk', without isolating single asci, as those are small and difficult to dissect. However, tetrad analysis is possible and was employed in early work. The power of resolution of the 'in bulk' genetic analysis has permitted fine structure mapping to the extent that mutations separated by 11 nucleotides have been resolved by recombination. *A. nidulans* strains carrying different markers can form heterokaryons. Nuclei in heterokaryons can rarely fuse, giving origin to stable diploids, which allow another layer of genetic analysis, developed by Pontecorvo and Etta Käffer, the parasexual cycle. Diploids can revert to haploids in which all markers in one chromosome segregate as a unit, allowing the rapid assignment to any new mutation to one of the eight chromosomes of the organism. Mitotic

recombination also occurs and can be selected for in diploids, permitting the mapping of markers in relation to the centromere. The discovery of the parasexual cycle led to two developments. The first one was the possibility to carry out genetic analysis in the *Aspergilli* and the related *Penicillia* where a sexual cycle was not described. It is not known why stable diploids, different from the transient diploids that occur during the sexual cycle, can be obtained in these organisms and not in other filamentous ascomycetes. The second was the analogous development of systems, initiated by Pontecorvo, and based on cell fusion to carry out somatic genetics in mammalian cells. *A. nidulans* entered the molecular era when relatively efficient transformation techniques were worked out in 1983 followed by the development of replicating plasmids. We are witnessing a second methodological revolution, with the development of techniques and modified strains that allow to inactivate genes, introduce point mutations, change promoters, or add tags in a very simple and rapid way, opening the possibility of a high throughput reverse genetics. This, together with the availability of a complete genome and microarrays is changing again the prospects for this model organism. Usually a technique is first worked out in *A. nidulans*, and then that is applied to the other *Aspergilli*, such as the pathogenic or industrially important organisms mentioned in previous sections. The life cycle of *A. nidulans* is shown in Fig. 4.

Work carried out with *A. nidulans* has served as a model mainly in three aspects of cell and molecular biology (but a few others will be briefly discussed below). Historically, each of these three aspects can be related to a specific scientific school. David Cove and John Pateman initiated the investigation on control of gene expression in *A. nidulans*. The cell biology work derives from an early article by Ron Morris (1976) where he isolated mutations blocked in the cell cycle and in nuclear migration. Bill Timberlake initiated an analysis of the development of the conidiophore, work which profited from the early genetic work of John Clutterbuck, himself a product of the Glasgow school of genetics. Work on secondary metabolism stems from a confluence of this work with work carried out in other species of *Aspergilli* producing noxious chemicals.

The Mitochondrial DNA of *A. nidulans*

The possibility to construct heterokaryons allows the genetic study of mutations that occur in the mitochondrial genome, as these are cytoplasmically inherited. A few markers were characterized and a circular genetic map was established. In the late 1970s, two groups, led respectively by Hans Künzel and Wayne Davies, attempted to sequence the whole 33,000 bp mitochondrial DNA of *A. nidulans*. This was almost accomplished, except for a gap of around 200 bp. At the time, where the longest DNA sequenced was

Fig. 4 Schematized life cycle of *Aspergillus nidulans*. Three cycles are shown, the asexual cycle, which has been described in the text (see *A. nidulans* as a model for cell biology and *A. nidulans* developmental pathways). In the sexual cycle, two nuclei divide synchronously as a dikaryon in a specialized structure. Eventually the nuclei fuse to give a diploid, which does not divide as such but undergo meiosis. No differentiated mating types exist; any given mycelium can generate fertile cleistothecia. To cross two strains, nutritional and color markers are used. Classical genetics procedures are facilitated by the fact that one cleistothecium derives from only one fertilisation event. In the parasexual cycle nuclei fuse in mycelia, outside the specialized developmental structure to yield a diploid, which does not undergo meiosis (at variance with diploids produced during the sexual cycle) but divides as such. Breaking up of the diploid (haploidization) and mitotic recombination are additional genetic tools. For clarity we have supposed that the heterokaryon and diploid formation are carried out between green (yA^+) yellow strains (yA^-) and nuclei are colored accordingly. Both diploids and heterokaryons can undergo the asexual cycle. The different structures are not shown to scale. Scheme kindly provided by Stéphane Demais and modified by the author.

the 16,000 bp mitochondrial DNA of *Homo sapiens*, this was a less than trivial enterprise. A number of important results derived from this sequencing effort. It was possible to compare the whole DNA organization with that of the completely sequenced human mitochondrial DNA, and the ongoing sequence of the *S. cerevisiae* mDNA, an organism where sophisticated genetic and molecular studies were actively carried out. These comparisons were extended to other mitochondrial DNA sequencing projects such as those of *Neurospora crassa*, *Podospora anserina*, and *Schizosaccharomyces pombe*. A number of unidentified open reading frames (ORFs) were found in the mitochondrial DNA of *A. nidulans* and the human mitochondrial DNA, but not on that of *S. cerevisiae* or of *S. pombe*. These reading frames correspond to genes coding for complex I, the NADH dehydrogenase complex, which is absent in both model yeasts. The highlight of this work was the elucidation of the structure of class I introns. Metazoan mitochondrial genes have no introns, while introns of two different classes are present in the mitochondria of fungi and plants. Introns on the nuclear genome of the fungi are small, typically of >100 bp. Mitochondrial fungal introns are large, usually >1000 bp, and can contain ORFs. A comparison of the sequences of the mitochondrial introns of *A. nidulans* with those of wild-type and mutant strain of *S. cerevisiae* led to a model of the secondary structure of class I introns, including the proposal of a mechanism of intron splicing. Around the same time, it was published that the intron of the precursor of the ribosomal 26s gene of *Tetrahymena thermophila* was self-splicing. It was noticed that pairings that were postulated by us and by Bernard Dujon and François Michel for mitochondrial group I introns were conserved in this self-splicing intron; thus the model for splicing of mitochondrial class I introns became a model of self-splicing, which was confirmed experimentally. Self-splicing of introns was essential to the concept of ribozyme and eventually to that of a primeval RNA world. Thus, the sequence of the mitochondrial DNA of *A. nidulans* contributed, albeit somewhat indirectly, to present ideas on the origin of life.

A. nidulans as a Model for Genetic Metabolic Diseases

The metabolic versatility of the Aspergilli led a group of Spanish scientists to use mutants blocked in amino acid degradation to identify the enzymes and the genes of human metabolic diseases, including those of aromatic and branched amino acid catabolism. As stated in a review article "The metabolic capacity of *A. nidulans* for amino acid degradation largely resembles that of human liver". Fig. 5 shows the breakdown of phenylalanine and the cognate blocks in human diseases affecting this metabolism. The gene of *A. nidulans* coding for the fumaryl-acetoacetate hydrolase was cloned as a cDNA highly expressed in the presence of phenylacetic acid (*fahA*, Fig. 5). Mutations in the human homologue result in the serious disease tyrosinemia I, and the *A. nidulans* ORF shows 47% identity with the human gene. Satisfactorily, the growth of *A. nidulans* is strongly inhibited by the accumulation of this metabolite in *fahA*-deleted strains. In a second step, suppressor mutations of this inhibited phenotype were isolated.

Fig. 5 *Aspergillus nidulans* as a model for human metabolic diseases. To the left the degradation of phenylalanine is shown, to the right of the pathway, the steps blocked in the cognate human metabolic diseases. In italics the relevant corresponding genes of *A. nidulans* are shown. To the right the toxicity of fumaryl-acetoacetate and the suppression of the toxicity by the upstream *hmgA* null is shown together with the secretion of the purple oxidation product of homogentisic acid. Lactose is used as a poor, nonrepressing carbon source, as phenylalanine catabolism is subject to carbon catabolite repression (see Section "Nitrogen and Carbon Utilization"). See text for details. Photographs of plates were kindly provided by Miguel Peñalva.

These pinpointed the gene (*hgmA*) coding for homogentisate dioxygenase. Not only these mutations suppressed the toxicity of phenylalanine seen in *fahA* nulls, they also resulted in the accumulation of a purple pigment (see Fig. 5). This is exactly the pigment that is accumulated in the urine of patients affected by a milder disease, alkaptonuria. The identification of the gene was straightforward and its sequence served to identify the hitherto unknown human gene and to identify the loss-of-function mutations present in a number of patients. Alkaptonuria was identified by Garrod in 1902 as an 'inborn error of metabolism' and shown to be inherited as single Mendelian gene. The work of Beadle and Tatum in *N. crassa*, and the one gene-one enzyme proposal arising from it, can be seen as a completion of Garrod early proposals. The identification of the human gene through the cloning of the *A. nidulans* gene is of more than historical importance and underlines the necessity of choosing the correct model system for a particular problem.

Control of Gene Expression

Nitrogen and Carbon Utilization

The Aspergilli can utilize a large number of metabolites as nitrogen and/or carbon sources. Early work with *A. nidulans* has established some fundamental concepts pertaining to the control of gene expression and metabolic regulation. Some of the first eukaryotic pathway-specific regulatory genes (*nirA*, *uaY*; see below) were characterized in the 1960s. The genes encoding the key regulators for nitrogen (*areA*) and carbon catabolite repression (*creA*) were the first such genes to be described in any eukaryotic organism. Their mode of action was established by formal genetic analysis long before recombinant DNA technology came into existence.

In general, the genes coding for the enzymes involved in the utilization of a specific metabolite are only transcribed in the presence of a specific inducer. Inducers act by activating specific transcription factors, which in turn elicit the transcription of specific catabolic genes. Thus, nitrate activates the NirA protein, necessary for the transcription of the genes encoding nitrate and nitrite reductase and the nitrate transporters, acetaldehyde activates AlcR, regulating ethanol utilization, uric acid activates UaY, regulating at least eight scattered genes encoding enzymes and transporters involved in purine utilization, proline activates PrnA, regulating all the other genes of the proline utilization gene cluster, while β -alanine activates AmdR/IntA a protein that positively regulates the *amdS* gene (encoding acetamidase) and the *gabA* gene (encoding the γ -aminobutyrate transporter).

Almost all the pathway-specific transcription factors belong to a group of proteins that bind DNA through a specific fungal motif, the Zn binuclear cluster (Cys₆Zn₂). Most bind DNA as dimers, including the paradigmatic *S. cerevisiae* protein GAL4. AlcR is an exception, which uniquely binds as a monomer. NirA and UaY are localized in the nucleus as a result of induction. Nitrate induces by breaking the association of NirA with KapK (the orthologue of the mammalian and *S. cerevisiae* exportins Crm1P and CRM1). PrnA and AlcR are always nuclear, PrnA necessitating induction to bind its cognate sequences in the promoter.

The induction of genes involved in the utilization of nitrogen sources does not occur in the presence of preferred sources such as ammonium and glutamine, while the induction of genes involved in the utilization of carbon sources is strongly diminished in the presence of glucose. These processes, nitrogen metabolite repression and carbon catabolite repression, involve two additional regulators, AreA and CreA. AreA is a GATA factor, acting positively in synergy with the specific regulators (such as NirA or UaY). Ammonium and glutamine negate AreA function at a number of levels, including the stability of its cognate mRNA. The dependence on AreA is absolute for the *niiA-niaD* bidirectional promoter, driving the genes encoding nitrate and nitrite reductases, less marked for some of the genes of the purine utilization pathway.

CreA acts as a genuine repressor in the presence of favored carbon sources, negating the activation by or competing with the binding of the pathway-specific factors such as AlcR.

CreA is a Zn finger protein, with a Zn finger sequence extremely similar to Mig1p, the repressor mediating carbon catabolite repression in *S. cerevisiae* and related organisms. However, the similarity between CreA and Mig1p stops there. Little sequence conservation can be seen outside the DNA-binding domain. Neither the glucose signaling mechanism nor the downstream mechanism of transcriptional repression seems to be shared by Mig1p and CreA. Mig1 represses transcription by recruiting the Tup1/Ssn6p co-repressor complex, which is not the case in *A. nidulans* and most likely in the fungi where a CreA, rather than a Mig1p orthologue, is present.

The Aspergilli can use a number of metabolites as both carbon and nitrogen sources, the mechanism of regulation having been elucidated for the *prn* gene cluster (comprising five genes involved in the utilization of proline) and the *amdS* gene. Repression occurs only when both repressing carbon (glucose) and nitrogen sources (ammonium or glutamine) are present. This can be rationalized by thinking that if a repressing nitrogen source is present, it will be advantageous for the organism to use proline or acetamide as a carbon source, while if only a favored carbon source is present, it will still be advantageous to use proline or acetamide as a nitrogen source. Carbon metabolite repression requires the CreA repressor, while nitrogen metabolite repression operates through the inactivation of the AreA GATA factor. While, for example, in the nitrate assimilation pathway AreA is always essential for transcription to occur, for *prn* and *amdS*, it is only necessary when the CreA repressor is activated by a repressing carbon source. These regulatory patterns are conserved in the Aspergilli and more generally in the filamentous ascomycetes and are schematized in Figs. 6–8, while the nuclear-cytoplasmic shuffling of NirA is illustrated in Fig. 9. The *gabA* gene, encoding the γ -aminobutyrate transporter, is subject to an even more complex pattern of regulation. It is induced by ω -amino acids and subject to concomitant repression by nitrogen, carbon, and alkaline pH.

Fig. 6 General scheme of the transcriptional regulation of genes involved in the utilization of nitrogen sources. (1) In the absence of a specific inducer (such as nitrate) and in the presence of a preferred, repressing nitrogen source (ammonium, glutamine), neither the specific transcription factor nor the broad-domain GATA factor AreA is activated. No or only basal transcription is seen. (2) In the absence of a specific inducer in the presence of a nonrepressive nitrogen source, only AreA is active. No or only basal transcription is seen. (3) In the presence of a specific inducer and in the absence of a repressing nitrogen source, both transcription factors are active, full transcription is seen. (4) In the presence of both a specific inducer and a repressing nitrogen source, the specific transcription factor is active, but the AreA factor is inactive and no transcription is seen. In the nitrate utilization pathway a further mechanism is in act, as AreA is necessary both indirectly through its regulation of transporters for the uptake of the specific inducer (nitrate) and for the binding of the specific transcription factor (NirA) to DNA. Thus, the situation will be identical to that seen in Scheme 1, at the top of this figure.

Fig. 7 General scheme of the transcriptional regulation of genes involved in the utilization of carbon sources. (1) In the presence of 'neutral' carbon source (such as glycerol) and the absence of an inducing carbon source, neither the specific positive-acting transcription factor nor the CreA repressor are bound to the promoter. No or only basal transcription is seen. (2) In the presence of an inducer carbon source, the specific transcription factor (such as AlcR in the ethanol utilization pathway) is bound to DNA and active, full transcription is seen. (3) In the presence of both inducing and repressing carbon sources, the specific transcription factor is active but the CreA repression partially or totally negates its effect. No or only basal transcription is seen. (4) In the presence of only a repressing carbon source, only the CreA repressor is bound to DNA, no or only basal transcription is seen.

Regulation of Gene Expression by External pH

Soil organisms, such as the *Aspergilli*, respond to a variety of environments and it is not surprising that a system that regulates gene expression as a function of external pH has evolved. External pH regulates genes coding for extracellular enzymes or transporters or those encoding steps in the synthesis of exported metabolites. In neutropenic mice experimentally infected with *A. nidulans*, this process is necessary for virulence. Penicillin is synthesized by some *Aspergilli* but only at alkaline pH. The synthesis and uptake of siderophores is also regulated by pH.

The elucidation of the mechanism of pH regulation is a superb scientific achievement of the groups of Herb Arst and Miguel Angel Peñalva. The signal transduction pathway described below is conserved throughout the ascomycetes. The key actor is PacC, a transcription factor of the classical Zn finger type. In its active form, PacC acts as a positive transcription factor of alkaline-expressed genes (such as alkaline phosphatase or isopenicillin synthase) and as a repressor of acid-expressed genes (such as

Fig. 8 General scheme of the transcriptional regulation of genes involved in the utilization of metabolites that can serve as both nitrogen and carbon sources. (1) In conditions where the inducer is not present the specific transcription factor (PrnA in the proline utilization gene cluster) is not bound to the promoter. In the scheme shown, under neutral conditions (e.g., urea as nitrogen source, lactose as carbon source) AreA would be bound, and CreA would not be bound. No or only basal transcription is seen. This applies to every other combination (not shown) where the specific inducer is absent. (2) Same conditions but in the presence of the inducer (proline in the example given in the text), both the specific transcription factor (such as PrnA) and AreA are bound, full transcription is seen. (3) In the presence of the inducer and a repressing nitrogen source (ammonium or glutamine) but no repressing carbon source. Only the specific transcription factor is bound. Full or almost full transcription. (4) In the presence of the inducer and a repressing carbon source (glucose), but no repressing nitrogen source. The three regulatory proteins are bound; AreA negates the repressing action of CreA. Full or almost full transcription. (5) In the presence of inducer (such as proline) and both carbon and nitrogen repressing metabolites (ammonium or glutamine and glucose). The specific transcription factor (such as PrnA) is bound and CreA negates its action. Efficient repression. No or only basal transcription is seen.

Fig. 9 Cytoplasmic and nuclear localization of the NirA transcription factor. A construction where the whole NirA transcription factor is fused to green fluorescent protein (GFP) substitutes the NirA wild-type gene. This construction is competent to mediate induction by nitrate. NirA is localized in the cytoplasm in the presence of a noninducing, nonrepressing nitrogen source (arginine), of a repressing nitrogen source (ammonium) and localizes in the nucleus only when an inducing nitrogen source is present. See text for details. This figure illustrates also the technology of gene fusions and epifluorescence microscopy, which is been extended to all other *Aspergilli* and many filamentous fungi, including animal and plant pathogens. The original pictures were kindly provided by Joseph Strauss.

acid phosphatase or the γ -aminobutyrate transporter). At acidic pH (pH usually tested 4.0), there is no activation signal, and the protein is in an inactive form. In the full-length PacC (PacC⁷²), intramolecular interactions hold the protein in a folded inactive form, which is largely excluded from the nucleus. At alkaline pH values (usually 8.0), the protein is activated by two proteolytic steps. The *palA*, *palB*, *palC*, *palF*, *palH*, and *palI* genes encode proteins involved in pH sensing and in signal transduction. Mutations in all these *pal* genes have an acidity-mimicking phenotype, while mutation in the transcription factor *pacC* can lead to acidity mimicking (loss-of-function mutations), alkalinity-mimicking or neutrality-mimicking phenotypes, where both 'alkaline' and 'acidic' genes are expressed. The pH sensor is probably PalH assisted by PalI, both of which are plasma membrane proteins.

The C-terminus cytoplasmic tail of PalH interacts directly with PalF, a member of the arrestin family, which is, similarly to the mammalian arrestins, phosphorylated and ubiquitinated. These modifications occur at alkaline pH and are dependent on the PalH and PalI proteins. Under alkaline pH conditions, PalA binds to motifs flanking a specific protease-sensitive sequence in the C-terminus of the full-length PacC (PacC⁷²). PalA interacts directly with the *A. nidulans* orthologue of Vps32, a protein involved in the formation of multivesicular endosomes. PacC/PalA interaction renders PacC sensitive to a specific cleavage, catalyzed by PalB, a protease of the calpain family. PacC⁷² is cleaved to PacC⁵³. The cleaved form of PacC becomes susceptible to further processing by the proteasome, yielding PacC²⁷. This is the active form of PacC, strictly localized in the nucleus, where it activates genes expressed at alkaline pH and represses genes expressed at acid pH. This account leaves open the mechanism of pH sensing and the connection between the arrestin-like PalF and PalA-PalB. The interactions of PalA with components of the mature endosome, and recent work on the related signal transduction pathway in *S. cerevisiae*, strongly suggests that endocytosis provides this connection. PalC, the unplaced actor of the process, has a functionally important Bro1 domain (also present in PalA), a domain of possible interaction with Vps32, strengthening the endosomal connection of the pH signaling pathway. The YPXL/I motif recognized by PalA is also recognized by its putative mammalian orthologue, AIP1/Alix, a protein involved in a variety of functions, including the budding of the human HIV virus from infected cells. The whole process has tantalizing similarities with the Hedgehog signaling pathway in metazoans, leading to the proteolytic activation of the Zn finger transcription factor *cubitus interruptus*/Gli, posing the question of whether these pathways are evolutionarily related. A simplified version of the pH signaling process is shown in Fig. 10.

Specific Regulatory Mechanisms Acting at the Level of Transporters

The control of transporter synthesis and activity is a key step in metabolic regulation, as the activity of specific transporters modulates the entry of metabolites that serve as inducers or repressors of specific pathways. Work with *A. nidulans* has led to the identification of two new control processes affecting transporters, besides their tight specific transcriptional regulation. The transcription of a number of transporters is activated during the isotropic phase of conidial germination (see below). This is a developmental control, which bypasses other specific control systems. Recent transcriptomic work suggests that this mechanism occurs for many transporters and is general for the filamentous ascomycetes. It can be proposed that germinating fungal spores explore an unknown environment by expressing a whole range of transporters, to progress to specific induction once the spore has germinated. The second mechanism is posttranslational. In the presence of a favored nitrogen source such as ammonium, both purine and amino acid transporters are internalized to the vacuole, where they are possibly destroyed. This posttranslational mechanism is synergistic with but independent from the nitrogen metabolite repression mechanism (described above). Fig. 11 illustrates this process.

Fig. 10 Simplified scheme of the regulation of gene expression by external pH, redrawn from a number of articles of the groups of Arst and Peñalva. Alkaline pH is sensed by the PalH and PalI proteins, the signal is transduced to the PalF arrestin via the C-terminus of PalH. PalF is phosphorylated and ubiquitinated and signals PalA, which has been shown to interact with the endosomal protein Vps32. The role of PalC is hypothetical. PalA leads to the opening of PacC⁷², which is cleaved by PalB at a specific site. PacC⁵³ is further processed by the proteasome, leading to the active form PacC²⁷. In this simplified scheme both proteolytic processing steps are shown in the cytoplasm, in fact the second step may occur in either or both the cytoplasm and the nucleus. In yellow, proteins of the pH signal transducing pathway, in blue cellular proteins or complexes nonspecific for the pathway. The 'active' portion of PacC is shown in green, the inhibitory, cleaved portions are shown in red.

Fig. 11 Posttranslational regulation of transporters. The left panel shows the membrane localization of a fusion with the green fluorescent protein of the proline transporter (PrnB-GFP). The cognate gene *prnB* maps in the proline gene cluster, its transcriptional regulation is schematized in Fig. 8 (see Section “Nitrogen and Carbon Utilization”). Conidiospores were grown for 16 h at 25°C in the presence of urea as nitrogen source, and induced with L-proline after 10 h. In the right-hand panel ammonium was added for the last 2 h. In the left panel, the PrnB-GFP fusion strongly stains also the basal septum. Localization in septa is a characteristic of all membrane proteins studied up to now. Confocal microscope images were kindly provided by Vicky Sophianopoulou.

Regulation of Secondary Metabolism

Fungi produce an astonishing variety of secondary metabolites. Fungal toxins, the β -lactam antibiotics and lovastatin, have already been mentioned. In the pregenomic days, conventional genetic analysis led to the identification, cloning, and sequencing of a number of genes encoding biosynthetic steps for a number of secondary metabolites, while many more metabolites were identified as secreted by a variety of *Aspergilli*. As many secondary metabolites involve nonribosomal peptide or polyketide synthases, putative fungal metabolite gene clusters have been identified in a number of fungal genomes. In *A. fumigatus*, the estimate is that of 22 secondary metabolite gene clusters. The best studied pathways are those leading to the biosynthesis of isopenicillin in *A. nidulans*, aflatoxin in *A. flavus*, and the aflatoxin precursor sterigmatocystin in *A. nidulans*. Secondary metabolism synthesis occurs late during mycelial growth and is generally correlated with conidiation and shares with this process some of its signaling pathway. Pathway-specific transcription factors have been characterized for the aflatoxin, sterigmatocystin, and gliotoxin pathways. The clusters of aflatoxin and sterigmatocystin biosynthesis include the regulatory gene *aflR*, necessary for the expression of the rest of the genes of the cluster. AflR belongs to the Cys₆Zn₂ family of specific fungal activators. It is not known whether the activation of AflR involves a specific metabolite or if it is only activated by the ‘fluffy’ signaling pathway to be described below (*A. nidulans* developmental pathways). No pathway-specific activator has been described for isopenicillin biosynthesis, which is regulated by a number of environmental parameters, including extracellular pH.

Clustering of genes is variable for genes involved in primary metabolism. In contrast, the genes of secondary metabolism biosynthesis are as a rule organised in large clusters. The 70 kb aflatoxin cluster comprises 25 coregulated genes. The gliotoxin gene cluster comprises 12 genes. Does the clustering of secondary metabolism genes have an evolutionary and/or functional significance? Possibly the two divergently transcribed genes responsible for isopenicillin-N synthesis have been horizontally transferred from a *Streptomyces* to an ancestor of the *Aspergilli* and *Penicillia*. There is no evidence for horizontal transfer for any other secondary metabolite gene cluster. Comparative genomics is providing some clues, even if not yet an answer, to the significance of secondary metabolite gene clustering. There is a significant bias toward the location of secondary metabolite clusters in subtelomeric regions. The fact that species of *Aspergilli* differ widely in the secondary metabolites they produce correlates with the mapping of the cognate genes in genomic regions where synteny between species is broken.

A fundamental advance in the understanding of the regulation of secondary metabolism arises from the discovery of the global regulator LaeA in the laboratory of Nancy Keller. LaeA is conserved in filamentous fungi, but not in yeasts. LaeA shows a domain typical of histone methyltransferases, the SAM domain, while lacking a second domain found in these enzymes, the SET domain. LaeA regulates positively the synthesis of isopenicillin, sterigmatocystin, gliotoxin, and lovastatin. The global role of LaeA has recently been investigated by transcriptomic studies with *A. fumigatus*. Of the 22 gene clusters, a deletion of *laeA* diminishes clearly the transcription of 13. Thus LaeA is a broad, but not a universal regulator of secondary metabolism. Recent work points to a role of LaeA in remodeling chromatin structure. In *A. nidulans*, deletion of a number of genes universally involved in gene silencing in heterochromatin result in premature secondary metabolite production. More strikingly, these deletions act as partial suppressors of a *laeA* deletion. Thus the exciting possibility arises that LaeA acts by reversing a heterochromatic state of the secondary metabolite gene clusters. Thus the study of the regulation of secondary metabolism may lead to an understanding of the role and genomic distribution of heterochromatin in filamentous ascomycetes.

A. nidulans as a Model for Cell Biology

The life cycle of the *Aspergilli* includes a number of tightly regulated developmental pathways, from the germination of conidia or ascospores to the formation of complex structures involved in sexual (cleistothecia) or asexual (conidiophore) spore formation. The germination of conidiospores, but not that of ascospores, has been well studied. Conidiospores can stay dormant and viable for many years and contain (in *A. nidulans*) one nucleus arrested in the G1 phase. When plated on suitable media, they go through a phase of isotropic growth, where the conidium swells. The first mitosis may occur in this phase or after the emergence of the germ tube (Fig. 12). Mitosis occurs synchronically, up to the eight nuclei stage when a perforated septum appears basally (Fig. 11). Other septa are laid during hyphal growth out every – three to four nuclei. Only the nuclei comprised between the septum and hyphal tip are competent to divide and they do so synchronously. A second germ tube can arise from the conidiospore at 180° from the first one. Nuclei in nonapical compartments became again competent to divide when the conidiophore is developed (see below) and when branches arise from subapical compartments. Thus a highly coordinated process occurs, involving the regulation of mitosis, the establishment of a primary polar axis, the establishment of secondary polar axes in branches, nuclear migration, the laying down of septa and finally the appearance of another highly polarized structure, the conidiophore. Some processes, such as hyphal polar growth and the deposition of septa, are specific of fungi, while others are common to all eukaryotes, and the *A. nidulans* work matches and has added considerable information to the work carried out in *S. pombe* and *S. cerevisiae*. In both yeasts and most cells in higher eukaryotes, mitosis is followed by cytokinesis, where the two daughter cells separate. This is not exactly the case in filamentous fungi, where the whole mycelium is one syncytium, subdivided by perforated septa. It must be stressed that during conidiogenesis the situation resembles budding, with proper cytokinesis, as metulae, phialides, and conidia are uninucleate cells, while ascospores are binucleate (see '*A. nidulans* developmental pathways'). Thus an understanding of *Aspergillus* cytokinesis involves understanding the generation of these different patterns. The determination of hyphal polarity and the related problem of the relationship of mitosis with septum formation are active fields of research at present, and recent work has shown that while some of the determinants of polarity and cytokinesis are common with the yeasts, some are entirely novel. In particular, a specific ceramide synthase is essential for polarity, probably by generating specific lipid rafts at the growing tip, which in turn would be involved in the localization of other polarity determinants such as formin, an actin nucleating protein. Particular to filamentous fungal growth is the Spitzenkörper, a subapical organelle that acts as a vesicle supply center. The challenge for future research is to understand the coordination of signaling pathways, the polarization of the actin cytoskeleton, the formation of lipid rafts, and the activity of the Spitzenkörper to reach a complete understanding of polarity determination.

Some of the highlights of the work relating to the cell cycle are indicated below, where *A. nidulans* has served as an eukaryotic model, while some specific aspects of *Aspergillus* development are summarized in '*A. nidulans* developmental pathways'.

The judicious use of mutants resistant to the tubulin inhibitor benomyl led to the identification of the first α - and β -tubulin-encoding genes in any organism. It was then shown that the tubulins are involved in nuclear and chromosomal movement. The crowning of this work was the discovery of γ -tubulin by Berl and Liz Oakley. A *benA* (encoding one of the isoforms of β -tubulin) temperature-sensitive mutant, *benA33*, results in microtubules that are hyperstable (rather than non-functional) at the nonpermissive temperature. Three suppressors of *benA33* mapped in a gene that when cloned and sequenced was shown to code for a new tubulin. This tubulin is critical for the nucleation of microtubules in all eukaryotes where it has

Fig. 12 Conidial germination. A group of germinating conidia from *A. nidulans* are shown. They are stained with the green fluorescent protein (GFP) fused to a strong nuclear localization signal, driven by a strong constitutive promoter. One white arrow indicates a conidia where the first mitosis has occurred before the production of the germinal tube, another mitosis occurring concomitantly with germination. Note that the signal is not lost during mitosis, which as in other fungi is closed. Photograph by Ana Pokorska in the laboratory of the author.

been studied. The establishment of the function of γ -tubulin illustrates the use of *A. nidulans* as a model organism. While the inactivation of the cognate gene is lethal, the mutation could be maintained in a heterokaryon (see Section “The *A. nidulans* Genetic System”). As conidia are uninucleate, heterokaryons will produce two types of conidia, one of which carries the disrupted allele, where the phenotype caused by the mutation during conidial germination can be assessed microscopically. The disruption does not affect germination, but blocks nuclear division and to some extent nuclear migration. DNA is replicated, chromosomes condense, but spindles are not assembled. Thus, work that started with the isolation of tubulin inhibitor-resistant mutants led to the discovery of a new tubulin, which in all organisms is crucial for microtubule nucleation in centrosomes and in fungi (which have a closed mitosis) in spindle polar bodies.

In the seminal Morris article of 1976, a large number of conditional mutants were characterized. These were temperature-sensitive mutants, which either failed to enter mitosis at the nonpermissive temperature (*nim*, never in mitosis), were blocked at different stages (*bim*, blocked in mitosis), or where the nuclei failed to migrate (*nud*, nuclear distribution), while *sep* mutants are defective in septum formation. Eventually, the cognate genes were cloned and sequenced, suppressors were isolated and identified, to give a growing picture of the genes involved in basic processes of cell biology.

Cellular motors of the myosin class associate with actin filaments, while kinesins and dyneins move cargo (vesicles and organelles) along microtubules. *nudA* encodes the dynein heavy chain, *nudG* the dynein light chain, while other *nud* mutants defined hitherto undescribed regulatory proteins of the dynein complex. In particular, *nudF* encodes a close homologue of the human protein LIS1, which is mutated in Miller–Dicker lissencephaly, a human hereditary disease of the nervous system where neurons fail to migrate in the hemizygote. NudC, a protein that interacts with NudF is also conserved from fungi to mammals. It is likely that the primary effects of NudC/NudF in organisms with an open mitosis are in cytokinesis, a role obviously that can only be partially conserved in a syncytial organism with a closed mitosis such as *A. nidulans*. This pioneering work, which exploited both the *A. nidulans* genetic system and its specific morphology, has guided the work leading to the understanding of the function of the dynein complex in the nervous system.

At variance with dyneins, kinesin genes are highly redundant and only one was identified through mutant screens. This is *bimC*, which defines a specific class of plus-end conserved kinesins. Mutants in this gene are defective in spindle pole separation and are thus blocked in nuclear division and provided the first direct evidence the kinesins are involved in mitosis.

In the genetic screen, no mutants blocked in G1 were found, mutants blocked in the S-phase map at five loci, others blocked in the transition of G2 to mitosis map at six loci. Among the genes so defined, some are orthologues of genes previously known from *S. pombe*. *nimX* (not identified in the screen) encodes the orthologue of the cyclin-dependent *S. pombe* cdc2 kinase. The homologue of the cdc13 cyclin B is encoded by *nimE*, while the phosphatase activity necessary for the activation of NimX^{cdc2} is encoded by *nimT*. NimA, on the contrary, is a newly discovered serine/threonine kinase, which defines a whole class of proteins conserved throughout the eukaryotes. NimA functions downstream of NimX^{cdc2}/cyclin B, which would then have two independent functions, one to promote spindle formation, through the activation of other kinases, the second to activate NimA, which in turn is necessary for chromosome condensation. NimA is necessary for entry into mitosis, mutants showing duplicated spindle polar bodies, while its destruction by proteolysis is necessary for exit from mitosis. There is a considerable evidence for similar roles in mitosis for NimA homologues in higher eukaryotes. A human protein, Pin1, interacting with NimA was identified in a two-hybrid screen. Pin1 mutants have a phenotype reciprocal to that of NimA mutants, suggesting that Pin1 (PinA in *A. nidulans*) is involved in the inactivation of NimA. Pin1 is a universally (in eukaryotes) conserved peptidyl-prolyl isomerase that catalyzes specifically the isomerization of prolyl bonds in a P-Ser/Thr-Pro dipeptide, increasing its rate by about 1000 times, thus allowing a drastic change in the peptide backbone conformation, NimA is only one of its substrates, another one being cdc2/cyclin B. It has recently been shown in HeLa cells that Pin1 is necessary for entry into mitosis, associates with mitotic chromosomes, and it strongly stimulates cdc2 phosphorylation. The discovery of Pin1 and its involvement in mitosis has led to flurry of activity, concerning its possible role in cancer, but more cogently in the onset of Alzheimer's disease. Mice homozygously deleted for the *Pin1* gene develop a neuronal degeneration with many of the histological characteristics of Alzheimer's. Both *tau*, a microtubule-associated protein, and APP (amyloid precursor protein) are phosphorylated at Ser/Thr-Pro motifs. These proteins are hyperphosphorylated and insoluble in Alzheimer's. It had been proposed that the key regulator of the state of these proteins is actually Pin1, which would displace the equilibrium toward the nonphosphorylated, soluble forms.

The anaphase-promoting complex (APC) is an ubiquitin ligase that targets key mitotic proteins such as cyclins and directs them to the proteasome. Mutants in its components will be expected to be blocked in metaphase and to show a *bim* phenotype. Two such components were first identified among the *bim* mutants. BimE was identified first as a negative regulator of mitosis. Biochemical work in *Xenopus* oocytes showed that a protein that copurified with APC (APC1) is the orthologue of BimE. *bimA* encodes the APC3 component. Once all chromosomes are attached to microtubules, APC activation results in degradation of securin. This releases and activates separase, a protease that cleaves cohesin. As cohesin keeps sister chromosomes together, this cleavage is the prerequisite for anaphase. *bimB* encodes separase. A component of cohesin, *sudA*, was identified as a suppressor of a *bimD* allele, which itself results in an anaphase block characterized for defective chromosome separation. Finally, mutations in *bimG* result in large, polyploid nuclei that fail to complete anaphase. Nuclei are clumped and conidia fail to germinate highlighting the link between the regulation of mitosis and the establishment of polarity. BimG is a phosphatase, showing striking identity with mammalian phosphatases of the PP1 class. BimG is localized to the spindle polar bodies, to the nucleolus, to the tip of the hypha, and transiently in the septum. There is no hint as to what are the substrates of BimG in the mitosis, septum formation, and polarity establishment.

A. nidulans Developmental Pathways

In the sexually reproducing *Aspergilli*, the mycelial mat can follow two different developmental pathways. Meiosis and the formation of asci that contain ascospores, occurs in specialized structures, the cleistothecia. In *A. nidulans*, mature cleistothecia are globose, darkly pigmented structures of 100–200 μm in diameter. Ascospores have a characteristic bivalve morphology (about $4\text{ }\mu\text{m} \times 3.5\text{ }\mu\text{m}$) showing two equatorial crests. Ascospore ornamentation is a valuable taxonomical character in the sexually reproducing *Aspergilli*. The protocleistothecium is generated from vegetative hyphae, which coil in a spherical structure developing into a cleistothecium, surrounded by specialized, modified hyphal cells called hülle cells. *A. nidulans* is homothallic; two genetically identical nuclei can fuse to give diploids which, as in all other filamentous ascomycetes, are immediately committed to meiosis. In heterothallic *Aspergilli*, the sexual cycle occurs only when nuclei of opposite mating types meet in heterokaryons. Some nonsexual *Aspergilli* (*A. flavus* and *A. parasiticus*) form structures, sclerotia, which may be developmentally related to the cleistothecium. Conceptually, we can distinguish two processes in the development of the mature cleistothecium. One is the morphological process that leads to cleistothecia, surrounded by hülle cells. The second is the behavior of nuclei, which in the primordium of the cleistothecium form dikaryons, in which two nuclei divide synchronously. Dikaryotic nuclei fuse into transient diploids, which undergo immediate meiosis, followed by two mitoses leading to eight binucleate haploid ascospores per ascus. These processes can be experimentally separated, as it is possible to obtain morphologically perfect cleistothecia that do not contain asci. Many genes, including transcription factors and G-coupled receptors, have been implicated in either or both processes. The availability of the genome and possibility of following tagged proteins through the developmental processes should lead to an understanding of the sexual maturation process, including the roles of mating types in homothallic and also heterothallic species. Very recent work has established that both α and HMR mating type genes (see Section “The Genus *Aspergillus* in the Genomic Era”) are necessary for fertility but not for cleistothecial formation. At present, we cannot yet draw a scheme of the developmental pathway leading to the formation of sexually mature, fertile cleistothecia.

The second developmental pathway is the formation of asexual conidia, which is present in all *Aspergilli*. These are formed from a specific structure, the conidiophore, which is the taxonomic marker of the genus. Conidiophores sizes range from 50 to 70 μm long in *A. nidulans* as much as 5 cm in *Aspergillus giganteus*. The structure of the conidiophore is shown in Fig. 13. From the flat mycelial mat, a stalk grows from a foot compartment at a right angle from the mat. The stalk then swells into a multinucleate vesicle. From the vesicle a first series of cells arise, the metulae or primary sterigmata. About 60 metulae are formed in each vesicle. Each metula buds at its tip to give two or three uninuclear phialides, also called secondary sterigmata. From the phialide, uninuclear

Fig. 13 The conidiophore of *Aspergillus nidulans*. In the left panel scanning electron microscopy images of conidiophore of the wild-type and two mutant strains are shown, these carry loss-of-function mutations in the *brlA* (bristle) and *abaA* (abacus) gene respectively. The center panel illustrates the developmental process by showing the expression of a membrane protein (the UapA transporter fused to the green fluorescent protein (GFP)), which is specifically expressed in the metula stage, which is then diluted on in the phialides and conidia, the same transporter is then expressed again during conidial germination (see text). The right panel shows a schematic representation of the conidiophore of *A. nidulans*, metulae and phialides are arbitrarily colored to facilitate identification. FC, foot compartment; S, conidiophore stalk; V, Vesicle; M, metula; P, phialide; C, conidia. Notice that for some metulae in the left and center panels the two cognate phialides can be clearly seen. The pictures in the left hand panel has been kindly provided by Reinhard Fischer. Reproduced with permission from Kues, U., Fischer, R. (Eds), 2006 The Micota I, Growth Differentiation and Sexuality. Berlin: Springer-Verlag. One of the center panel by George Diallinas and Areti Pantazopoulou.

conidia bud, only one nucleus enters each conidium. The process is repeated, in such a way that clonal rows of conidia are formed, the last conidium to be formed is adjacent to the metula, the first and oldest being the most distal one. This process is not identical in all *Aspergilli*; some species, called uniseriate (such as *A. fumigatus*), have only one series of sterigmata from where conidia arise directly, while in some *Aspergilli*, conidia contain more than one nucleus (such as *A. oryzae*).

Two approaches were used to study this process. In the first one, mutants were isolated and blocked in different steps of conidiophore development; in the second, mycelia were synchronized, and by the technique of 'cascade hybridization', an early methodology to define a transcriptome, it was determined which genes were expressed at different stages of conidiophore development. John Clutterbuck published in 1969 the seminal article of the study of the conidiophore developmental pathway, while the first cascade experiment in any organism was published by the Timberlake Laboratory in 1980. Clutterbuck described a number of mutants blocked in different steps of conidiophore development. In *bristle* mutants (*brlA*), conidiophore stalks that fail to complete the developmental pathway originate from the mycelial mat. In *abacus* mutants (*abaA*), sterigmata continue to give row after row of additional sterigmata, without ever terminally differentiate phialidae or conidia (Fig. 14). *Stunted* mutants (*stuA*) result in short conidiophores with conidia being made directly from the vesicle, while in *medusa* (*medA*), metulae do not immediately differentiate and produce series on metulae before giving origin to phialides. Finally, *wet* mutants (*wetA*) do not affect the development of the conidiophore, but result in defective conidia that autolyze. Once these genes were cloned, their function was analyzed by inactivating them, following their expression pattern and overexpressing them conditionally using the tightly regulated *alcA* promoter (see above). BrlA is a Zn finger transcription factor, which directly regulates the expression of *abaA*. AbaA is also a transcription factor, which regulates *brlA* in a feedback loop and *wetA*. WetA regulates late-expressed and conidial-specific genes such as cell wall genes, and it is supposed to be a transcription factor. StuA has the characteristics of a transcription factor and limits in some unknown way the spatial distribution of the BrlA and AbaA proteins as well as being involved in conidiophore elongation and wall thickening, while MedA regulates the temporal expression of *brlA* along the developing conidiophore. Downstream of the three core regulators, BrlA, AbaA, and WetA, there are target genes, which are activated at different stages of the conidial developmental process. Some of these, as genes involved in spore pigmentation, were known from the earlier days of *A. nidulans* genetics, others were identified by the cascade hybridization methodology. These target genes show a variety of regulation patterns, some like *wA* (see Fig. 14) being under the control of WetA, some like γA under the control of AbaA, some others requiring, in order to be expressed, various combinations of the three transcription factors. The number of downstream genes has been estimated <100 by genetical procedures and at about 1200 by cascade hybridization. This huge difference could be partly explained by the

Fig. 14 Simplified scheme of the development of the conidiophore. The central developmental pathway, involving the products of the BrlA, AbaA, and WetA transcription factors is shown. In blue, target genes. Three are specifically shown, *rodA* encoding a conidial specific hydrophobin (see Section “*Aspergillus* as Human Pathogens”), γA encoding the last step of the synthesis of the wild-type green pigment and *wA*, encoding a polyketide synthase which is the first step in the synthesis of the conidial pigment. The insets show the morphological phenotypes of *veA1*, *brlA*, *abaA*, *wetA*, γA , and *wA* mutations. To the right a simplified version of the signalization pathway defined by dominant and recessive fluffy mutations. The inset shows the morphological phenotype of a fluffy mutant. The transmembrane receptor of the FluG signal has not been identified. The insets correspond approximately to the size of colonies grown on complete medium at 37°C for 48 h. Pictures from the laboratory of the author or kindly provided by Reinhard Fischer. All signals are shown as affecting the expression of *brlA*, but this is for simplicity's sake, as we do not know if these are direct or indirect. PkaA may affect the BrlA protein posttranslationally. To simplify the scheme the β and γ subunits interacting with FadA are not shown.

fact that the inactivation of at least some sporulation-specific genes does not lead to any visible phenotype and that overexpression of many metabolic genes occurs during sporulation.

This scheme does not account for the signaling pathway that leads to the onset of conidiation, that is, the formation from the mycelial mat of the conidiophore stalk. All the early work was carried out in a standard Glasgow strain, which is really a hyperconidiating constitutive mutant carrying the *veA1* mutation. This partial loss-of-function mutation leads to profuse conidiation in the dark. In strains carrying this mutation, when the mycelia are transferred from submerged culture to an air interphase, conidiation occurs synchronously in the dark, which allows the monitoring of the expression of relevant genes. The *veA*⁺ (wild-type) strains behave quite differently. In these strains, conidiation is light inducible, and *veA*⁺ strains produce profusely cleistothecia in the dark. *veA* null mutants do not produce cleistothecia at all. Blue light irradiation result in exclusion of the VeA protein from the nucleus, whereas the VeA1 mutant protein lacks precisely the nuclear localization signal and is always present in the cytoplasm. VeA mediates also, directly or indirectly, the response to polyunsaturated fatty acids, which have been shown to provide a sporogenic signal that is alternative or additive to light, the ratio of different unsaturated fatty acids driving development toward the sexual or the asexual cycle. The *veA* gene product behaves formally in the absence of light as a repressor of conidiation and an activator of cleistothecial development. Thus, VeA must directly or indirectly repress the expression of *brlA*. Fig. 13 and Fig. 14 illustrate and summarize the process of conidiophore development.

In order to study the signalization of *brlA*, another set of mutants was isolated. These are strains where a conidiophore does not develop, 'fluffy' mutants, which make a fast growing, colorless, undifferentiated mycelium. The study of fluffy mutations has revealed a complex signaling pathway, which determines both the conidiation pathway and the production of secondary metabolites. Recessive mutations of the *fluG* gene lead to a fluffy phenotype. FluG codes for an enzyme that is responsible for the synthesis of a diffusible product, which activates, through an unknown receptor, a signaling cascade specified by several *flb* genes. Dominant mutations in the *fadA* gene also lead to a fluffy phenotype. FadA is a subunit of a trimeric G-protein, which in its GTP-bound form activates a protein kinase (PkaA) that through phosphorylation of target proteins represses secondary metabolism, promotes growth, and represses conidiation. The FlbA protein, also characterized by fluffy loss-of-function mutations, acts downstream of the FluG signal to shift FadA to the GDP-bound inactive form. Fig. 14 summarizes the 'fluffy' signaling pathway and its possible relationship with the developmental pathway leading to conidiation. Recent work has shown that the 'fluffy' class of mutations has not been saturated and that there are at least three concurrent signaling pathways. This complex signaling pathway (which has been drastically simplified here and in Fig. 14) conceals, however, a conceptual problem. Fluffy mutants are not only aconidial but they are also foremost, fast proliferating mutants. By studying fluffy mutants, we are studying the signals that control and limit mycelial proliferation, and the complete or partial loss of conidiation could be a necessary result of the enhanced proliferative activity. In fact, if we slow down the growth of fluffy mutants by using very poor carbon sources, quite good conidiation can be seen. Mutants that are specifically altered in the signals upstream of bristle should not be fluffy, but 'bald', where conidiophores do not arise from a normally proliferating mycelial flat mat. However, 'bald' mutants were not reported in the early mutant screens, and it will be most interesting to know if they could be isolated at all.

The Genus *Aspergillus* in the Genomic Era

In the last few years, complete genomic sequences have been established for *A. nidulans*, *A. oryzae*, *A. fumigatus*, *A. terreus*, two different strains of *A. niger*, *A. flavus*, *Aspergillus clavatus*, and *Neosartorya fischeri* ('perfect' name for *Aspergillus fischerianus*). Articles have been published describing the genomes of *A. nidulans*, *A. fumigatus*, *A. oryzae*, and *A. niger*. Dedicated Web sites exist for all the species except for the ongoing projects of *A. clavatus* and *N. fischeri*; the predicted genes and proteins of the latter can be found in the NCBI database. For *A. nidulans*, where a detailed genetic map exists, a correlation of the genetic and physical maps is available, even if the *in silico* identification of many of the classically mapped genes with autocalled genes is far from complete. Genome annotation is in different stages of completion in different species and so is the availability of microarrays. The availability of complete genomes has stimulated technological developments that allow high throughput gene inactivation and substitution. The genomes reflect the high metabolic versatility of the genus and have highlighted the evolutionary divergence of the different species. Telomeres have been assigned to each *A. nidulans* chromosome and this can be carried out for all the other member of the genus. Putatively active transposons of different families have been identified, including the interesting finding that helitrons, a newly described family of rolling-circle replicating eukaryotic transposons, are present and active in *A. nidulans* but not in the other species. The last release of the *A. nidulans* genome predicts 10,701 proteins as coded by the genome of this species, while for *A. niger*, the predicted number is 14,165. Interestingly, all the genomes sequenced contain mating type genes and other genes known or presumed to be involved in the sexual cycle. The homothallic *A. nidulans* and *N. fischeri* contains unlinked genes for both the α and HGM mating types, but their location in the genome suggest that homothallism has evolved independently in these species. Interestingly, for *A. fumigatus*, *A. oryzae*, and *A. flavus*, strains of opposite mating types have been found in nature, opening the possibility that in fact all (or at least many) Aspergilli can undergo the sexual cycle. Another interesting finding is the variability and phylogenetic scatter of the genes putatively involved in the production of secondary metabolites. As an example, the genome of *A. niger* contains a gene cluster similar to that involved in the synthesis of fumonisin in *Gibberella* (*Fusarium*) *moniliformis*, while these genes are absent in other Aspergilli, thus positing the question of whether convergent evolution or horizontal transfer is involved. The considerable knowledge accumulated in *A. nidulans* may permit to extrapolate to other Aspergilli, for example, by asking which

are the genes regulated by transcription factors such as NirA, AreA, or PacC (see Section “Control of Gene Expression”), investigate promoter structure *in silico*, or more subtly to investigate the factors that make the conidiophore of *A. nidulans* biserial, that of *A. fumigatus* uniserial and that of *A. clavatus* characteristically elongated and uniserial. At present, genome data have grown faster than the capacity of the research community to make use of them, a general problem of the genomic era. It is hoped that the comparison of genomes will lead to a better understanding of problems such as the evolution of metabolism, the evolution of the sexual and parasexual cycles, the evolution of silencing mechanisms, the isolation of useful new secondary metabolites, the possible engineering of pathways to produce new metabolites, and the identification of specific fungal essential genes that could lead the development of highly specific antifungal agents.

Appendix A: *Aspergillus*: A Multifaceted Genus. 2018 Update

Introduction

In 2007 (3rd edition of the Encyclopaedia of Microbiology, published 2009), there were 26,641 Pub Med entries for “*Aspergillus*”, today (October 2018), there are 46,233. In 2007 the genomes of *A. nidulans*, *A. oryzae*, *A. fumigatus*, *A. flavus*, *A. fischerianus* and *A. niger* were available. A recent article reports the genome analysis of 19 species. The Joint Genetic Institute includes 85 genomes of *Aspergillus* species, together with genomes of many other related organisms such as *Penicillium* and *Monascus* spp. Species Fungorum, a taxonomical site maintained by Kew Gardens, has 823 records for different *Aspergillus* species, from *A. acanthosporus* to *A. zutongii*. In 2017, 37 new species of *Aspergillus* were described. Thus, to update our knowledge of the genus *Aspergillus* is a daunting task. I thus apologise if some of my choices of the work reported appear somewhat subjective.

Contrary to what I have stated, Pier Antonio Micheli was not ordained as a catholic priest. Poor, and with no formal education, several priests and friars stimulated his vocation as a naturalist. Besides being considered “the father of Mycology” Micheli devised (1729), following Redi on flies (1668) but preceding Spallanzani (1765–1767) and Pasteur (1864) ingenious experiments leading to the disproving of spontaneous generation. His contribution went far beyond descriptive mycology and has a place in the history of the experimental method. In his experiments, he used a *Botrytis* sp. and a *Mucor* sp., together with “*Aspergilli capitati, capitulo glauco*”, which could have been *A. fumigatus* or *A. glaucus*. This work was the very first use of *Aspergillus* (and other fungi) as model organisms to investigate a general biological problem. The most accessible account of the experimental work of Micheli is G.C. Ainsworth, *Introduction to the History of Mycology* (1976), reissued by Cambridge University Press. Even for us who don’t read Latin, the *Nova plantarum genera*. . . of Micheli, 1729 (an example on Fig. 1, left panel, chapter printed above, third edition), can now be downloaded from the library of the Royal Botanical Gardens in Madrid, I will follow up some of the sections of the 2009 publication, and try to point out major advances for each of these.

What are the Aspergilli, taxonomy

The dual nomenclature of “perfect” and “imperfect” forms has almost died out. On the whole, the term *Aspergillus* is used for all species. In 2012, the international commission on *Aspergillus* and *Penicillium* decided: “Option 5: Compromise: Keep the name *Aspergillus* (as option 2), and treat other names as optional when it has a meaning (but always together with the *Aspergillus* name).” In practice, almost everyone uses *Aspergillus*. *Aspergillus* is, within the fungi, a genus in the phylum Ascomycota, sub-phylum Pezizomycotina, Class Eurotiomycetes, Order Eurotiales, Family Trichomomaceae. All evidence points out to the genus being monophyletic.

Food contamination by Aspergillus

Aflatoxin B1 is metabolised in the liver to an 8,9-exo-epoxide derivative. It is this derivative which is mutagenic and carcinogenic. Hepatitis viruses (mainly Hepatitis B) and chronic exposure to aflatoxin are strongly synergic in the development of hepatocarcinoma. In 2013 a major scare followed the finding of levels of aflatoxins above the permitted threshold in milk in Holland and Germany. Apparently, this originated from animal feed imported from Serbia. No further negative consequences for human health were reported. Aflatoxin poisoning may not only be a disease of poverty, but also a result of globalisation.

Aspergillus (mainly *fumigatus*) as human pathogens

While concentrating below on invasive pulmonary aspergillosis, the actual number of cases of the non-life-threatening Allergic Pulmonary Aspergillosis and Chronic Pulmonary Aspergillosis conditions (the latter affecting mainly patients with a previous, underlying lung disease) is actually far higher than those with invasive pulmonary aspergillosis. Invasive Pulmonary Aspergillosis continues to be a major pathology for immunocompromised patients, the mortality rate being >50%. It is still not clear why *A. fumigatus* is the major species involved. However, patients suffering from chronic granulomatous disease (a genetic condition resulting from mutations affecting any of 5 sub-units of NADPH-oxidase) are uniquely sensitive to invasive infection by *A. nidulans*. Ability of *A. fumigatus* to form biofilms contributes to pathogenicity and drug resistance. Melanin presence in the conidiospores, hydrophobicity of the latter and early production of the toxic gliotoxin are still considered contributing factors. The exopolysaccharide galactosaminogalactan (GAG, a linear polysaccharide composed of galactose bound to N-acetyl galactosamine in no specific arrangement) has shown to be essential for adherence of *A. fumigatus* hyphae to both cells and artificial substrates, while also masking cell wall antigens, thus suppressing host inflammatory responses. Mutants deleted for the epimerase gene necessary for GAG synthesis (*uge3*) are critically impaired in virulence in mice. Orthologues of *uge3* are present throughout the Aspergilli (84% identity with *A. nidulans*) and GAG is present in many fungal species, including *A. nidulans*. However, the amounts of mycelial cell-wall bound GAG are significantly higher in *A. fumigatus* and the relative amounts of N-acetyl-galactosamine in the polymer are also higher. An early expression of *uge3* during conidial germination, could be actually a long-sought-for specific pathogenicity factor. A consensus seems to have been reached that there are no specific pathogenic factors, but rather a serendipitous constellation of characteristics in this species has pre-disposed it to become an opportunistic pathogen.

I correct an inaccuracy in the 2009 version of this article. The specificity of 5-fluorocytosine to inhibit fungal growth is based on its conversion to 5-fluorouracil by cytosine deaminase, an enzyme absent in human cells. However, toxicity affecting both liver and

bone marrow has been reported. It is not widely used in the treatment of Aspergillosis, as *A. fumigatus* is not very sensitive to it, due to the repression of the cognate transporter at physiological pHs.

It is essential to develop new antimycotic agents, given the appearance of azole resistant strains. *A. fumigatus* resistant strains are present in the environment, in all probability due to the widespread use of azoles in agricultural practice. Nevertheless, *in patient* resistance can also arise. The most common genotype of pan-azole resistance strains includes a tandem duplication of the promoter region of *cyp51* (encoding lanosterol 4- α -demethylase) leading to eight-fold overexpression of the gene, together with a mutation in the ORF, L98H being the most frequent. Advances in treatment have relied mostly in developing new azoles and echinocandins and/or new ways to deliver already currently employed drugs. Nevertheless, new agents targeting specific aspects of fungal metabolism are being developed, among these specific inhibitors of cell wall. Some newly developed Nikkomycins, inhibitors of chitin synthases are in Phase 2 clinical trials. The most promising new antifungal drug, VL2397, produced by *Acremonium perscinum* is effective against *A. fumigatus*, and is undergoing Phase 2 clinical trials. It was discovered by a brute force screen, which used infected silk-worms (larvae of *Bombix mori*) as the test-organism. The mechanism of action of VL2397 is not known, but it is structurally similar to siderophores (Fe³⁺ chelators) and is incorporated into the mycelium by siderophores transporters. Siderophore synthesis is well known and essential for *A. fumigatus* pathogenicity. The latter has suggested a possible “trojan horse” approach where an antimycotic drug is conjugated with a siderophore, which then delivers it to the fungal cell.

Aspergillus sydowii as a gorgonian coral pathogen

Recent work has disproved the existence of specific pathogenic strains of *A. sydowii*. A study including both morphological and molecular markers did not find any evidence favouring the “African dust hypothesis”. The snail *Cyphoma gibbosum*, a specialist predator of gorgonian corals, may be responsible from spreading the disease. While the prevalence of the disease was quite alarming shortly after its discovery in 1995, the epizootic outbreak has now subsided to relatively low endemic levels. Selection of resistant gorgonian corals, is supposed to have been the main mechanism for this outcome.

Extracellular enzymes produced by *Aspergilli*

An exciting development is the very recent isolation and characterisation of a strain of *A. tubingensis* (a member of the *A. nigr*i -black *Aspergilli*- group) able to degrade polyester polyurethane (PU). It was estimated (2006) an annual global production of 8 million tons of PU increasing by 4%–5% year. PU is usually disposed in land-fills (forbidden in several European countries) or burned with the production of both carbon monoxide and hydrogen cyanide. To determine the detailed enzymology and the regulation of the process, together with the possible use of *A. tubingensis* in PU bio-degradation, alone or within a microbial community, would be of obvious importance.

Aspergillus nidulans as a model organism

The reverse genetics of the *Aspergilli* has seen a number of methodological advances. Transformation can be carried out now directly with composite DNA molecules assembled from PCR products. Arguably the most useful advance has been the availability of strains (first obtained for *Neurospora crassa*) inactivated for the *nkuA* gene, necessary for non-homologous end-joining recombination, thus virtually eliminating the problem of non-homologous integration in transformation experiments. Transformation frequencies were improved for a number of *Aspergilli* by direct transfer of the Ti plasmid of *Agrobacterium tumefaciens*, which can also compete with or complement transposon-based methods for random inactivation of genes. Recently CRISPR-Cas9 methods have been adapted to a variety of *Aspergilli*. The advances on reverse genetics had the effect of displacing research -at least in quantitative terms- from the model organism *A. nidulans* to species of industrial or medical importance, as these methods partially by-pass the need for sophisticated classical genetics. For 2018 there are in PubMed (up to October), 112 entries for *A. nidulans* compared with 486 for *A. fumigatus* and 369 for *A. niger*.

A number of fluorescent proteins are available to generate fusions to investigate cell trafficking and intracellular protein-protein interactions. This, coupled with striking advances in cell imaging has allowed extremely sophisticated studies of the cell biology of filamentous fungi with *A. nidulans* and *N. crassa* as the key model organisms. The articles of many of the groups working on *Aspergillus* cell biology are routinely accompanied by high-quality movies showing intracellular traffic.

I will detail below some recent contributions to fundamental cell and molecular biology based on work with *A. nidulans*. Progress has been achieved in understanding the signaling of some of the regulatory proteins mentioned in the 2009 version of this article (see Figs. 6, 7 and 8 of the 2009 edition printed above, and related text pages). The activation of the CreA repressor, mediating carbon catabolite repression is complex and surely different from that of that of the isofunctional Mig1p of *Saccharomyces cerevisiae*. A ubiquitination/de-ubiquitination cycle is involved in the activation of CreA in *A. nidulans*. The positive-acting GATA factor AreA responds to the presence of favored nitrogen sources through several mechanisms. An important one is RNA stability, intracellular glutamine destabilising the *areA* mRNA. The protein mediating this process, and also the degradation of other mRNAs involved in the utilization of nitrogen sources, RrmA has been identified. RrmA is quite conserved even in very basal fungal species such as *Rozella allomyces* (Cryptomycota) and even in Oomycetes (Stramenopiles, related to brown algae), organisms with a “fungal lifestyle”, some of which are important plant pathogens.

Fig. 9 of the 2009 edition printed above shows the nitrate-induced localization to the nucleus of NirA, the specific transcription factor necessary for the expression of the three genes of the nitrate utilization gene cluster. Strauss and co-workers have shown that in

the absence of nitrate, a conserved methionine in the Nuclear Export Sequence is oxidised to methionine sulfoxide by a specific enzyme. Nitrate elicits the reduction of the oxidised methionine, nuclear localization and activation of NirA. While the intramolecular structural changes resulting from this oxidation/reduction cycle are not yet elucidated, sulphoxidation of methionine is a novel signaling mechanism, probably conserved throughout the nitrate induction mechanism in the Pezizomycotina.

The continuing work of the laboratories of Miguel Peñalva and Herb Arst have led to a more profound understanding of the signaling pathway leading to the activation by proteolysis of the transcription factor PacC, illustrated in Fig. 10 of the 2009 edition. Endocytosis, as it was then proposed, is not involved, but nevertheless, the ESCRT complexes (Endosomal Sorting Complexes Required for Transport) participate in PacC activation. The ESCRT multi-protein complexes, conserved throughout eukaryotes, mediate multi-vesicular body biogenesis, a process which internalise membrane proteins into endosomes leading to their eventual degradation in vacuoles. They are involved in other processes such as membrane excision during cell division and viral budding. In alkaline conditions, the ubiquitinated PalF binds to PalH and recruits proteins of the ESCRTI and ESCRTII complexes. These, in turn recruit the ESCRTIII protein Snf7/Vps32 (*S. cerevisiae* nomenclature, shown in Fig. 9 of the 2009 edition, printed above to bind PalA in the cytoplasm, see below). The polymer of Snf7 interacts with a PalA/PalC complex that in turn recruits PalB, the protease which catalyzes the first proteolytic step leading to the activation of PacC. The whole process occurs in a plasma membrane-bound rather than a cytoplasmic location as proposed previously and shown in Fig. 9 of the 2009 edition, printed above. Data from related work in *S. cerevisiae* and the basal yeast species *Yarrowia lipolytica* point to an overall conservation of this signaling pathway in the ascomycetes. An unresolved problem is how PalH senses extracellular pH, leading to its binding of PalF. The signaling of pH regulation in fungi, provides a further example of the multiple cellular functions of the ESCRT complexes. This work led to the discovery of a novel signaling system involved in cation homeostasis. Mutations in genes encoding proteins of the ESCRT complexes lead to severely impaired growth. Suppressors of this phenotype map in two genes, *sltA* and *sltB*. These encode respectively a Zn-finger transcription factor and protease/pseudokinase self-activating protein, required for SltA activation. SltA and SltB are required for cation tolerance; mutations in either *slt* gene also result in oversized vacuoles. The range of targets of SltA includes both vacuolar and plasma membrane cation transporters. Another transcription factor CrzA, regulated by the calcineurin/calmodulin system also participates in cation homeostasis. CrzA is widely conserved among eukaryotes, while the SltA system is specific to the Pezizomycotina, a sub-phylum of the Ascomycota (see above).

Post-translational regulation of transporter fate is now well established (Fig. 11 of the 2009 edition, printed above). A new phenomenon, endocytosis as a direct result of transport activity has been shown for the uric acid-xanthine transporter of *A. nidulans*. Several *A. nidulans* transporters have been dissected by mutagenesis coupled with molecular modelling of docked substrates. The highpoint of this work has been the determination of the actual structure of the UapA xanthine/uric acid transporter complexed with xanthine. Substrate specificity is determined by the interaction of the substrate binding domain with gate domains along the substrate translocation pathway. The structure confirms predictions based on mutational evidence and strongly suggests an "elevator model" where in a UapA dimer, a core domain which binds the substrate sliding down a dimerisation/gate domain, thus leading to the internalisation of the substrate (cartoon in Fig. A1).

Work with *S. cerevisiae* has defined specific compartments in the cell membrane. One of these (MCC), containing the arginine transporter Can1p is organised thanks to a number of other proteins, some tetraspan membrane proteins such as Sur7 and Nce102, others localized immediately below the membrane. These are two BAR domain proteins which generate furrows in the membrane called eisosomes, which typically appear as punctate structures. Eisosomes were described as sites of endocytosis in *S. cerevisiae*, but

Fig. A1 A very schematic cartoon of the elevator model which accounts for all the structural and mutational data obtained for the UapA transporter. Grey, core domain which includes substrate binding residues. Blue, gate/dimerisation domain which includes both gate residues, which limit substrate specificity, and the dimerisation surface. Red star, substrate of the transporter. The core domain slides and twists around the dimerisation domain, transporting the ligand from the extracellular space (up, left scheme) to the cytosol (down, right scheme). A similar model accounts for the properties of the bacterial uracil transporter UraA, a member of the same transporter family (NAT) as UapA. I thank Sotiris Amillis and George Diallinas for help with this figure.

Fig. A2 Left panel: A model of the PilA eisosomal protein of *A. nidulans* (blue) superposed to the solved cartoon structure of the LspA protein of *S. cerevisiae* (red) showing the typical BAR domain structure. Model obtained with I-Tasser (Yang, J., Yan, R., Roy, A., et al., 2015. The I-TASSER Suite: Protein structure and function prediction. *Nature Methods* 12, 7–8) and visualised with VMD 1.9.4 (Humphrey, W., Dalke, A., Schulten, K., 1996. VMD - Visual Molecular Dynamics. *Journal of Molecular Graphics* 14, 33–38). Right panel: Eisosomes in a 14 h germling of *A. nidulans* grown at 25°C. Top, DIC, Middle, PilA-mRFP fusion protein fluorescence, Bottom PilA-mRFP three dimensional reconstruction. Scale bar 5 μ m. Picture courtesy of Alexandros Atanasopoulou and Vicky Sophianopoulou. Detailed methods to be found in the recent publication of these authors.

recent work points out rather to a protective role in relation to endocytosis. Eisosome organization has been studied sparingly in a few other species, but in detail in *Aspergillus nidulans*. There are two BAR domain eisosomal paralogues in the Aspergilli, PilA and PilB. Eisosomes in conidia and ascospores contain both PilA and PilB, while mycelial eisosomes include PilA but not PilB. Eisosomes are quite an enigma, as the cognate proteins are almost universally conserved in ascomycetes, but their deletion has virtually no phenotype (Fig. A2).

The laboratory of Steve Osmani has established the fate of all nuclear pore components during mitosis in *A. nidulans*, his results challenging the traditional drastic opposition of closed and open mitosis processes. Further collaborative work with the laboratory of Eduardo Espeso has aimed to establish the role and fate during mitosis of the 14 putative nuclear transport (importins and exportins) proteins found in the genome of *A. nidulans*. This work identified six essential nuclear genes involved respectively in a general protein import pathway, a general nuclear export pathway, an mRNA/nucleoprotein export pathway and a possible specific carrier of the RanA GTPase. Hydrolysis of GTP, catalyzed by RanA, provides the energy for all nuclear entry/exit transactions. The essential proteins studied remain partially attached to the nucleus or nuclear envelope during mitosis. The KapK/CrmA export pathway had been previously shown to mediate NirA and AreA localization while the importin $\alpha 1/\beta 1$ is responsible for the import of VeA. The detailed knowledge of nuclear import/export pathways coupled with that of the role transcription factors involved in metabolism, cell cycle and morphogenesis would allow a unique thorough description of nuclear entry/exit processes coupled with gene expression in this organism.

The Golgi apparatus of *A. nidulans*, studied in detail in the laboratory of Miguel Peñalva, is a dynamic network, which is polarized early during apical extension and remains intact during mitosis. They have also established that the biogenesis of secretory vesicles fuelling apical extension is governed by the recruitment to the trans-Golgi network of the RAB11 GTPase, which is mediated by the TRAPP II oligomeric GTPase exchange factor (GEF). This latter finding is of general importance as RAB11 function in the establishment and maintenance of polarity during development has been established in several animal systems, including human cells, *Xenopus* and *Drosophila*.

The filamentous nature of the Aspergilli (and in general all Pezizomycotina as opposed to the single celled yeast models) and their growth by apical extension implies an active directional intracellular traffic. *A. nidulans* has been, together with *N. crassa* the model to study these processes. Molecular motors (dynein, kinesins, myosin-5) are involved in the long-distance movement of organelles, such as secretory vesicles, early endosomes and peroxisomes. Classical and molecular genetic analysis together with newly developed imaging techniques is leading to a complete analysis of the growing hyphae, defining the role of exocytosis and endocytosis at the hyphal tip. One substantial advance is the molecular and functional definition of the Spitzkörper. This German term, coined in 1924, referred to dark staining organelle at the tip of hyphae. The Spitzkörper results from an accumulation of secretory vesicles involved in exocytosis and hyphal expansion at the apex before fusing with the plasma membrane, and thus can be considered as the organelle determining hyphal apical extension.

Aspergillus mitochondrial genomes

Total genome sequencing necessarily includes mitochondrial DNA and thus it is possible to assemble and compare these genomes within and outside the genus. A systematic approach for all available *Aspergillus* mitochondrial genomes has not been carried out. The comparison of mitochondrial genomes of six species of *Aspergillus* and three of *Penicillium* showed a variation in size mostly due to class I introns, proteins encoded in their open reading frames and “accessory genes”, that is mitochondrial encoded genes of

unknown function. Curiously, *A. nidulans* where very early work on the mitochondrial genome, intron positions and structure was carried out, was not included in this survey.

Secondary metabolites and their synthesis

The availability of whole genome sequences led to the realisation that only a small minority of fungal secondary metabolites (SM) had been detected by standard chemical methods. The genes encoding SM synthetic enzymes are usually clustered and they include as a key enzyme a polyketide synthase and/or a non-ribosomal peptide synthase (such as that catalysing the condensation of L- α -amino adipic acid, L-cysteine and L-valine into a tripeptide in the synthesis of the penicillins). The presence of SM gene clusters is extremely variable even between different strain of the same species. This had led to the development of informatic programmes to detect secondary metabolism gene clusters. Genome analysis has led to the identification of 56 SM gene clusters in *A. flavus*, 26 in *A. fumigatus* and 56 in *A. nidulans*. This is probably the tip of the iceberg. The potentiality of *Aspergilli* to produce novel compounds is illustrated by the identification in 2017 of *A. hancockii*, (a member of the *flavus* group) which when cultured on rice, produces, besides a number of hydrolytic enzymes, 69 secondary metabolites, of which 11 were novel. Gene clusters involved in SM metabolite synthesis can be organised in different patterns. In *A. fumigatus* trichothecene synthesis genes are split in two clusters, while a single super-cluster, regulated by *LaeA* encodes the enzymes involved in the synthesis of the unrelated, fumitremorgin, fumagillin and pseurotin, the latter two in an interwoven (Fig. A3).

Under standard laboratory conditions most of SM gene clusters are not expressed. We are faced here with two problems, one conceptual and one practical. The first is to identify and dissect the signaling which leads to the expression of each secondary metabolite gene cluster. The second, is to elicit the expression of each cluster under controlled conditions, such as to be able to assay the biological activity of each of the many yet undescribed secondary metabolites. These are problems not specific to the *Aspergilli*, as secondary metabolites gene clusters are present in fungi, bacteria and plants, and perhaps in other poorly studied microbial eukaryotes. The most obvious method is to try as many culture conditions as feasible and monitor the metabolites produced by standard chemical methods. Transcriptome analysis could then be used to identify the cognate genes or gene clusters. Many secondary metabolite gene clusters include a specific transcription factor gene. Its overexpression being a straightforward way to activate the gene cluster. The overexpression of *laeA* led to expression of several secondary metabolite gene clusters. Heterologous expression of SM genes, coupled with the substitution of native promoters by inducible, well characterized ones, has been used to investigate the products of several polyketide synthases and has led to the elucidation of the biosynthetic pathway of the *A. fumigatus* meroterpenoid pyripyropene, a potentially useful inhibitor of cholesterol synthesis. A promising avenue is the construction of gene libraries of ≈ 100 Kb in a multi-copy, self-replicating plasmid, comprising potentially each of the SCM gene clusters in a given genome, followed by transformation and expression in *A. nidulans*. Using this methodology (FAC-MS, Fungal Artificial Chromosomes-Metabolic Scoring) seventeen SC metabolites from different *Aspergilli* were identified and assigned to their cognate gene clusters. Finally, the expression of some SM clusters was achieved serendipitously. In a forward mutation screen, *laeB* (not a paralogue of *laeA* see above) was identified, where a deletion results in loss of sterigmatocystin synthesis but also unexpectedly in eight new secondary metabolites being produced. The deletion of a protein kinase (*mpkA*, see below, genomic section) resulted in the activation of the Asperindin A gene cluster in *A. nidulans*. Life-saving (penicillin) or deadly (aflatoxin B) fungal secondary metabolites were at first discovered serendipitously. Statins were discovered after a systematic search of HMG-CoA reductase inhibitors in the culture broths of 3800 strains of fungi. This illustrates the problem of trying to find a function and/or application of the plethora of secondary metabolites produced by fungi and revealed by genome screens. A combination of methods, both bioinformatic and experimental high-throughput screening will be necessary to address this challenge.

The importance of chromatin organization in secondary metabolism gene expression is under active investigation and has revealed a role for the Compass complex (involved in methylation of H3K4), histone deacetylation, H3K4 and K9 methylation and heterochromatin protein I in secondary metabolite gene cluster silencing. The link between secondary metabolism and developmental regulation has been brought to the forefront with the discovery that *LaeA*, a global regulator of secondary metabolism, forms a complex with VeA and a VeA-like protein, VelB. As established previously, VeA is enriched in the nucleus in the light, but the distribution of *LaeA* and VelB does not seem to be affected by light/dark conditions. This physical interaction was unexpected and opens a new avenue of research. In a thorough screen several new positive regulators of secondary metabolism cluster were discovered. A global negative-acting putative DNA binding protein, McrA was detected in *A. nidulans* and is conserved in many other ascomycetes. McrA seems to be a global regulator, involved in the repression of other genes beside secondary metabolite gene clusters. A cogent model linking the function of *LaeA* in secondary metabolism production with the light-regulated roles of VeA in

Fig. A3 A complex secondary metabolism gene cluster of *A. fumigatus*. Partial view of a sub-telomeric region of chromosome VIII of *A. fumigatus*. All the genes in this cluster and the near-by cluster involved in the biosynthesis of fumitremorgin are regulated by *LaeA*, and those shown in the figure also by the specific transcription factor encoded by *fapR* (in blue in the scheme). In red, genes encoding enzymes involved in fumagillin biosynthesis; in green genes, involved in pseurotin biosynthesis, interspersed yellow genes involved in neither, but nevertheless *FapR*-regulated. I have indicated the names of only the two “signature” genes, *fmaB* encodes a polyketide synthase, *psoA* a hybrid polyketide synthase non-ribosomal peptide synthase. Redrawn and simplified from Wiemann, P., Guo, C.-J., Palmer, J.M. et al., 2013. Prototype of an intertwined secondary-metabolite supercluster. *Proceedings of the National Academy of Sciences of the United States of America* 110 (42), 17065–17070.

the shift from the asexual to the sexual cycle is not yet available, neither is a comprehensive scheme of how the different positive and negative regulators interact.

While several environmental signals may be involved in triggering secondary metabolite production, a quite striking finding is that at least some secondary metabolite biosynthesis can be triggered by a close direct interaction of *A. nidulans* with *Streptomyces hygroscopicus*. Conversely, a non-identified *Aspergillus* species secretes a specific bacteriostatic metabolite (structure known, but biosynthetic pathway and genes involved not determined), which turns on the synthesis of nitrous oxide by a non-identified, co-cultured *Streptomyces* species, which activates the biosynthesis by the bacterium of a fungistatic agent, heronapyrrole B. These two studies underline the importance both conceptual and practical of studying secondary metabolism production in relevant ecological settings.

Aspergillus asexual sporulation

The pathway leading to the differentiation of the conidia in *A. nidulans* as shown in Fig. 14 of the main text still holds with some additional complications and refinements.

Research has proceeded in two directions. In the first, the details of the pathway signaling the key transcription factor BrlA were ironed out. To somewhat simplify, the central role of BrlA is confirmed, different paths leading of conidiogenesis are different ways of turning on *brlA* transcription. The Velvet complex responds to environmental stimuli, such as blue and red light, carbon levels, exposure of the hyphae to the atmosphere, osmotic and/or oxidative stresses, which lead to VeA cytoplasmic as opposed to nuclear localization, with resulting de-repression of the asexual sporulation pathway.

The "FluG factor" (Fig. 14) can be bypassed by an adduct of dehydroaustinol (a meroterpenoid) and diorcinol (a derivative of the secondary metabolite orsellinic acid). As the adduct is lypophilic, it may go through the membrane without the need of a specific receptor or transporter, which would leave open the identity of the intracellular interactor of the adduct.

In Fig. 14 of the main text it is indicated that a number of genes called *flb* (for fluffy, low *brlA* expression) are involved in the signaling of *brlA*. FlbB is a basic-leucine zipper transcription factor which is targeted to the hyphal apex, where it complexes with FlbE. The latter is essential for the apical localization of FlbB. In response to an unknown signal (perhaps mediated by the hypothetical receptor of the FluG signal) FlbB detaches itself from FlbE, travels in a retrograde fashion and eventually into the nuclei of aerial cells. FlbB transit through the apex is a prerequisite for its transcriptional competence, which was unexpected. Once inside the nucleus, FlbB elicits the synthesis of FlbD, a transcription factor of the cMyb-type. A dimer of both cooperate with a third transcription factor, of the Cys2His2 type, FlbC, to turn on *brlA* transcription. Uniquely among the Flb and Flu proteins, FlbD is also required for the formation of the peridium, the wall of the sexual fruiting bodies. In addition to the central regulators showed in Fig. 14 a number of negative regulators of asexual sporulation have been identified. SfgA, is Zn⁺⁺2 Cys6 factor (motif called Cys₆ Zn₂ in page 411, shared by a large number of fungal transcription factors). SfgA represses the FlbB/D/C pathway, epistasis relations indicate that FluG acts relieving SfgA repression. VosA belongs to the same family as VeA and acts in vegetative growth by repressing *brlA*, finally NsdD is a repressive GATA factor, which on the other hand is necessary for sexual development. The latter two factors act by repressing *brlA*. A simplified scheme is shown in Fig. A4. A number of viruses (see below) affect conidiation of different species of *Aspergillus*. The interaction of these viruses with the asexual sporulation pathway is an unexplored area of research.

The second direction is to investigate how general is the conidiation induction pathway worked out for *Aspergillus nidulans*; within the Aspergilli and beyond. The first approach is obviously genomic, that is, to investigate which components of the conidiation cascade are present in which species. Some of these genes are not limited to the Aspergilli, or indeed to the Pezizomycotina. Twentyfive genomes species of *Aspergillus* show a complete conservation of the genes involved in asexual sporulation. The central regulatory network composed by *brlA*, *abA* and *wetA* is conserved almost without exception throughout the searched *Aspergillaceae*. Once relevant genes are identified in a given species, standard methods could be used to check if their function is conserved. An example of this work is the investigation of the role of transcriptional activator WetA in *A. nidulans*, *A. flavus* and *A. fumigatus*. This work included RNAsec and Chip-sec (see below). The repression feed-back loop of *brlA* by WetA (not shown in Fig. 14 of the main text) is common to the three species, as it is the conidial color-less and autolysed phenotype. However, a number of downstream target genes are species specific. Previous work had established a pervasive role for WetA in *A. flavus*, including in vegetative growth. Travelling far away from the Aspergilli, in the wheat pathogen *Zymosteria tritici* (Pezizomycotina, Dothideomycetes) genome we find homologues of many of the genes involved in the sporulation pathway in the Aspergilli, including the central regulator *brlA*. Systematic deletion of these genes revealed that the orthologues of *abaA*, *brlA* and *flbB* do not have a crucial role in asexual sporulation, while *stuA* deletions failed to produce spores. This illustrates the limits of model systems and that apparently orthologous genes can be used in different ways in developmental pathways.

Fig. A4 The complex regulation of the expression of the *brlA* gene. This figure complements Fig. 14 of the 2009 edition, printed above. In red negative regulators and in green positive regulators of expression. Red connectors, repression, green arrows induction of expression. The squiggle arrow indicates the role FlbE in FlbB apical localization.

Aspergillus Sex

For an old-fashioned mycologist, this title would be an oxymoron, as *Aspergilli* by definition don't have sex, and when they have, they also have to change name. Following the cogent phylogenetic evidence that the apparently non-sexed *Aspergilli* and their sexual relatives form a monophyletic clade, I will discuss them together. In the original article I mentioned sex in two contexts, first while describing the sexual cycle of *A. nidulans*, which led to its development as a model organism, secondly in the context of developmental pathways. The mutational approach, which was a resounding success in the dissection of asexual sporulation has not delivered such a cogent picture for the process of fruiting body (cleistothecial) formation, in spite of some interesting mutations having been characterized. It seems clear, however, that the formation of fruiting bodies, differentiation of hülle cells and fertilisation/nuclear fusion and meiosis are separable processes. It may be necessary to summarize again the process of sexual reproduction in the Pezizomycotina, the sub-phylum of the ascomycetes to which the *Aspergilli* belong. This has clear differences with other ascomycetes, the "yeasts" (properly Saccharomycotina and Taphrinomycotina). In specialised structures, two nuclei, which could be of the same or of different strains, divide synchronically in a common cytoplasm. This stage is called the dikaryon. Fertilisation occurs when the two nuclei fuse, giving origin to a diploid nucleus. This nucleus never divides mitotically, but goes immediately into meiosis resulting in four haploid cells. These may divide once more mitotically, typically resulting in eight ascospores, contained within an ascus (sack). Asci of *A. nidulans* comprise eight bi-nucleate ascospores (Fig. A5). *A. nidulans* is a homothallic species, no strains of different mating types are extant. Heterothallic ascomycetes came in two mating types and only strains of opposite types can mate. This is the case for *S. cerevisiae* and *Schizosaccharomyces pombe*, yeasts, which follow a different path to meiosis without the dikaryon stage (see above). Two heterothallic *Aspergilli* *A. (Neosartoria) fennelliae* and *A. (Emericella) heterothallicus* were described about 50 years ago. In heterothallic ascomycetes mating type is determined by alternative genes (called idiomorphs), which are non-homologous but occupy, however the same chromosomal location (I am ignoring here the silent mating type loci, present in some yeasts, and which underlie mating type switching as they are not relevant to this discussion). These two genes encode DNA binding proteins comprising two different domains. One mating type gene encodes an α -box protein (MAT1-1 abbreviated MAT1). The alternative mating type gene (MAT1-2, abbreviated MAT2) encodes a protein including a HMG-box (high mobility group-box). There are usually several paralogues of HMG proteins in the genome (e.g., 7 in *A. nidulans*) of which one is concerned with determining the mating type. In the genome of the homothallic *A. nidulans*, both HMG-box and α -box encoding genes are present in different chromosomes and necessary for the sexual cycle, while in the "asexual" *A. fumigatus* and *A. oryzae* only the HMG-box encoding gene and only the α -box encoding gene were detected respectively. This was coherent with *A. nidulans* being homothallic, but suggested that the other two species were heterothallic rather than asexual, and it was a serendipitous occurrence which mating type was found in the single sequenced strain. Indeed, targeted sequence of many isolates of *A. fumigatus* yielded strains with either one or other mating types. In *N. fischeri* (*A. fischerianus*) a homothallic species of the *Fumigati* group, both mating type genes are present. In a more recent survey comprising 18 *Aspergillus* species, all species were found to have either one or the other mating type (thus possibly being heterothallic), while in addition to *A. nidulans* and *A. fischerianus* *A. glaucum* also has both. All species genomes included the pheromone and pheromone receptor encoding genes first described in *A. nidulans*. Thus, probably none of the species involved in this survey is asexual. Population genetics studies had suggested

Fig. A5 Left panel, shows partial contents of a crushed cleistothecium. In the center an entire ascus with eight brown-red pigmented ascospores. To the left of it, an ascospore from a broken ascus. The large pale round cells are hülle cells. Right panel: Isolated ascus, top light microscopy, center epifluorescence of nuclei labelled with histone H1 fused to a red-fluorescent protein, bottom merge of top and central panels. recombination in *A. fumigatus*, *A. flavus* and *A. parasiticus*. The discovery of strains of the same species with complementary mating types led directly to attempts to obtain sexual crosses in the laboratory. This was strikingly successful for *A. fumigatus* (which led to a suggested name change to *Neosartoria fumigata*, unfortunate in my opinion) and successively for a few other species, including members of the biotechnologically important black *Aspergilli*, such as *A. tubingensis*. We should start doubting whether asexual *Aspergilli* exist at all. Similar work has been carried out with *Penicillia*, and some other members of the *Pezizomycotina*. There has been an unresolved debate, as to which of the modes of sexual reproduction (homothallic or heterothallic) is primitive and which derivative. The two mating types should not be confused with the fact, that when crossing two strains of *A. nidulans*, distinguished by genetic markers, in any one cleistothecium either nucleus can behave as a “female” or “male” nucleus. Both mitochondrial markers and nuclear markers with a maternal effect have been used to establish this fact, which was known from classical genetical work, but has not been investigated further.

Viruses of *Aspergillus*

I did not address this subject in the original article, but recent work prompts me to include it here. Following work with *Penicillium*, it was published in 1970 that both *A. niger* and *A. foetidus* (a close relative and probably a strain of *A. niger*) contain viral particles and that double stranded RNA extracted from these was able to elicit interferon production in mice. Double stranded RNA viruses were reported in a number of *Aspergillus* species. No extracellular transmission seems to occur. Transmission was achieved through heterokaryons, and also between species through protoplast fusion. Most viral infections are asymptomatic. This contrasts with the well-studied killer phenotype of *S. cerevisiae*, which is caused by a dsRNA. Interspecies transfer to *A. nidulans* showed that one specific RNA virus suppressed the dicer-argonaute silencing pathway, while a second one actually was degraded to siRNAs, presumably through the action of dicer. Recently there has been a revival in the search and study of double stranded viral RNAs, using multiplex RNAseq. Most of the recent work concerns *A. fumigatus*. Many strains of *A. fumigatus* were screened for dsRNAs which revealed viruses belonging to several different families. Some alterations of morphology were reported, but no glaring correlation with pathogenicity or fungicide resistance was found. The virology of the *Aspergilli* is an underexplored area, mainly in respect of the phenotypic effects of viral infection. Old work (some of it of the 50s) showed cytoplasmic transmissible morphological phenotypes in a number of *Aspergilli*. The correlation of these with viral infections deserve a re-investigation.

Aspergillus in the post-genomic era

In the original article I referred to the “genomic” era of *Aspergillus* research. It has now become customary to refer to “post genomics” to highlight the challenges posed by an accumulation of data that goes beyond the capabilities of a research community. I have referred throughout this update to the contribution that genome availability has made to different research areas (SM, Asexual and sexual sporulation, fate of nuclear envelope proteins). *Aspergillus* is arguable the genus with most genomes sequenced and annotated. The availability of a genome does not automatically lead to the knowledge of the proteome. Gene models, derived from genome sequencing are based on algorithms that detect the start and end of open reading frames and the intron/exon structure of each gene in the genome. The latter is a particularly vexed problem. In spite of the existence of algorithms trained on different species, it is not uncommon to find erroneous gene models in data bases. I have personally encountered spuriously fused genes, promoters interpreted as introns, dubious start codons and incorrect intron/exon organization. While alternative splicing is less frequent in fungi than in other eukaryotes; it does occur, including in the *Aspergilli*, and to detect it is essential to establishing a complete correct proteome. Correct gene models are essential to interpret proteomes obtained under different conditions analyzed by mass spectrometry. The corollary of genome availability is transcriptomics, and “next generation” sequencing techniques (RNAseq) have displaced other methods to investigate global gene expression. The application of RNAseq to the complete transcriptome has two objectives, firstly, to obtain correct gene models for all genes in a given genome. Secondly, to establish the transcriptome under different growth conditions or at different developmental stages. Whole transcriptomes are available for *A. nidulans*, *A. flavus*, *A. oryzae*, *A. niger*, *A. fumigatus* among others. These were used to investigate general metabolic competence, secondary metabolism gene expression, developmental switches, resting conidia, response to drugs and alteration of expression in response to specific mutations and the transcriptional competence of specific transcription factors. As an example, FlbB mentioned in the context of asexual sporulation (see above), has other functions including the positive regulation of four secondary metabolism gene clusters. It is also possible to draw the complete chromatin landscape of a specific genome, combining chromatin immunoprecipitation (ChIP) microarray hybridization (Chip-Chip) or by parallel sequencing of precipitated DNA (Chip-Seq). Chip-Seq has been used to study the histone H3 acetylation profile of *A. nidulans* co-cultivated with *S. rapamycinicus* (see above Section “Regulation of Secondary Metabolism”), which led to the discovery of BasR a Myb-like transcription factor, which mediates the response to co-cultivation.

In both *S. cerevisiae* and *N. crassa*, knock-out strains are available for every gene. In *A. nidulans* knock-out cassettes can be obtained from the Fungal Genetics Stock Center. Using this methodology, all kinases of *A. nidulans* were deleted, and the phenotypes of their deletions studied. In principle such throughput methods can be used for any single gene family or groups of genes.

The availability of whole genomes has contributed to establish phylogenetic relations within the *Aspergilli* and of the *Aspergilli* with other fungi. A very recent article reports whole genomes for 23 species of *Aspergillus* section *nigri*. The availability of genomes opens new areas of *in silico* research. The evolution of gene clustering goes beyond secondary metabolism. Pre-genomic work has shown clustering in a number of primary metabolism pathways in *A. nidulans*, usually absent in *S. cerevisiae* and *N. crassa*. Comparative genomics allows the study of how clustering arises, changes and vanishes within and beyond the genus.

An example of this is provided by recent work on the nicotinate utilisation gene cluster of *A. nidulans*. Horizontal gene transfer (HGT) within eukaryotes is subject to controversy. There is no question that, notwithstanding our ignorance of its mechanism, transfer within the fungi, to the fungi and beyond has occurred. Already mentioned was the transfer of genes involved β -lactam synthesis from a *Streptomyces* to an ancestor of *Aspergilli* and *Penicillia*. Examples derived from genome analysis are the acquisition by *A. niger* fumonisin gene cluster from a *Fusarium* sp. and the acquisition by *Podospira anserina* (Sordariomycetes) of the sterigmatocystin gene cluster from an *Aspergillus*. Algorithms have been developed to detect HGT and applied specifically to *Aspergillus* species (HGT-finder). This predicts, as an example, 715 possible HTG events for *A. nidulans*. SM genes are over represented in this sample which confirms previous proposals. However, specific, individual phylogenies are necessary to validate the findings of HGT-finder. As for other taxa, the availability of whole genomes reveals a surprising role for HGT in genome evolution and metabolic capabilities. An untapped area is the evolution of transposable elements, limited recently to an investigation of LINE (long interspersed nuclear elements) retrotransposons in strains of *A. fumigatus*.

Autotrophic CO₂ Metabolism[☆]

Birgit E Alber, Ohio State University, Columbus, OH, USA

© 2019 Elsevier Inc. All rights reserved.

Glossary

Autotrophy Self-feeding, is the ability of an organism to synthesize all cell carbon constituents exclusively from inorganic carbon. Therefore, if an autotrophic organism was to be grown in the presence of labeled CO₂, every single carbon in the cell would become labeled (except the ones derived from essential growth factors added to the medium).

Carboxylation is the addition of CO₂ or bicarbonate to another carbon-containing molecule, resulting in a carbon-carbon bond.

CO₂ assimilation Describes the biosynthesis of cell carbon constituents (biomass) starting from carbon dioxide or bicarbonate.

CO₂ fixation Describes the conversion of CO₂ (a gas) to an organic compound containing carbon-carbon bonds as well as the assimilation of this CO₂ fixation product.

Heterotrophy Organic compounds are used as carbon sources.

Inorganic carbon species Used in autotrophy are carbon dioxide (CO₂), bicarbonate (HCO₃⁻), but also carbon monoxide (CO) or cyanide (CN⁻).

Primary production Is the formation of organic compounds from inorganic carbon species using light or chemically-derived energy.

Introduction

Over the past years, since the publication of the last edition of the *Encyclopedia of Microbiology* in 2009, there have been several advances in our knowledge of microbial autotrophy. A sixth pathway for autotrophic carbon fixation, the dicarboxylate/4-hydroxybutyrate, has been described. New tools have been developed to access the distribution of the different pathways for CO₂ fixation. This aids in assigning the contribution of specific autotrophic organisms in biomass production for a given habitat.

This chapter, however, not only focuses on recent progress in the field of autotrophic CO₂ metabolism, but aims also to present a comprehensive overview of this area of microbiology.

Autotrophic Modes of Life

The biosynthesis of organic carbon starting from inorganic carbon species by autotrophic organisms is a prerequisite to sustain life. The complete oxidation of organic carbon compounds to CO₂ by heterotrophic organisms allows the maximum gain of reducing equivalents, which can be transferred to a terminal electron acceptor such as oxygen, nitrate, and sulfate for energy conservation. CO₂ fixation by autotrophic organisms refills the organic carbon pool. When CO₂ assimilation is viewed as the reversal of carbon oxidation to CO₂ this process then requires: reducing equivalents and some input of energy. Because CO₂ is the sole source of carbon for autotrophic organisms, reducing equivalents and energy cannot be obtained by oxidation of an organic carbon substrate. (Formate and methanol oxidation and re-assimilation of carbon dioxide by some aerobes can be viewed as an exception of autotrophy). Instead the source of reducing power is provided by inorganic compounds such as water, hydrogen, reduced sulfur compounds, reduced metal ions or ammonium. Likewise, energy is provided by photosynthesis or by the reduction of oxidized inorganic compounds such as oxygen, nitrate, oxidized metals or sulfate. Primary production (using light or chemical energy), therefore, occurs in aerobic as well as in anaerobic environments. Members of all three domains of life, *Bacteria*, *Archaea*, and *Eukarya* are able to thrive autotrophically. It is important to remember, however, that CO₂ assimilation in *Eukarya* (terrestrially quantitatively most important in land plants) is of microbial origin, as the chloroplasts from such organisms are thought to have arisen from a cyanobacterial endosymbiont.

Conversion of Inorganic Carbon to Cell Carbon

Overall Equation

The general equation for cell carbon biosynthesis from CO₂ is the same for any given organism, because the average oxidation level of the carbon of any cell is close to zero (equal to oxidation state of formaldehyde, CH₂O). However, the amount of adenosine

[☆]*Change History:* August 2014. BE Alber introduced small edits in the text of the article including citations, added the sections 'Applications' and 'References', and added Figures and Table.

This article is an update of B.E. Alber, Autotrophic CO₂ Metabolism, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 18–31.

triphosphate (ATP) required is dependent on the mechanism used for CO₂ assimilation as well as the electron donor used (see below). Therefore, autotrophic CO₂ fixation follows the general reaction scheme:

Synthesis of Precursor Metabolites

When considering the biosynthesis of all cell constituents from CO₂, it is sufficient to understand the synthesis of specific intermediates of central carbon metabolism that are the starting molecules leading to all building blocks of the cell. These so-called precursor metabolites include acetyl-CoA, oxaloacetate, 2-oxoglutarate, pyruvate and 3-phosphoglycerate. There are presently six CO₂ assimilation sequences known: the reductive pentose phosphate cycle (Calvin-Bassham-Benson cycle), the reductive acetyl-CoA pathway (Wood-Ljungdahl pathway), the reductive citric acid cycle (Arnon-Buchanan cycle), the 3-hydroxypropionate/malyl-CoA bicycle (Holo-Fuchs bicycle), the 3-hydroxypropionate/4-hydroxybutyrate cycle, and the dicarboxylate/4-hydroxybutyrate cycle. These autotrophic pathways account for the net synthesis of acetyl-CoA (reductive acetyl-CoA pathway, reductive citric acid cycle, 3-hydroxypropionate/4-hydroxybutyrate cycle, and the dicarboxylate/4-hydroxybutyrate cycle), pyruvate (3-hydroxypropionate/malyl-CoA bicycle) or 3-phosphoglycerate (reductive pentose phosphate cycle) from either CO₂ or bicarbonate. The further conversion of acetyl-CoA to C₃- or C₄-compounds is not discussed in detail here, but in each case the reductive carboxylation of acetyl-CoA to pyruvate, catalyzed by pyruvate synthase (pyruvate:ferredoxin oxidoreductase), has been proposed. The conversion of pyruvate to the C₄-compound oxaloacetate proceeds either by direct carboxylation (pyruvate carboxylase) or via carboxylation of phosphoenolpyruvate (PEP) catalyzed by PEP carboxylase. The C₅-compound 2-oxoglutarate is formed from acetyl-CoA and oxaloacetate by enzymes of the oxidative citric acid cycle or via a (complete or incomplete) reductive citric acid cycle.

CO₂ Concentrating Mechanisms

The concentration of dissolved CO₂ at pH 7 under an air atmosphere is only about 10 μM. Ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBisCO), the major CO₂ fixation enzyme, has *K_m* values for CO₂ that range from 10 to 300 μM. In addition, RuBisCO has a rather slow turnover even at saturating levels of CO₂; this enzyme also catalyzes an apparent wasteful competing oxygenation reaction in the presence of oxygen. Carboxysomes provide a microenvironment for RuBisCO with locally elevated CO₂ (and most likely decreased oxygen) concentrations. The function of these protein microcompartments were first suggested for *Halothiobacillus neapolitanus* (formerly: *Thiobacillus neapolitanus*), an aerobic thiosulfate oxidizer and obligate autotroph. Similar cellular inclusions, albeit with different structural components, were found in oxygenic phototrophic cyanobacteria. Carboxysomes consist of several different proteins, among them specific shell proteins, carbonic anhydrase (catalyzing the interconversion of bicarbonate and CO₂), and the majority of the cellular RuBisCO enzyme. In addition to carboxysomes, there are various CO₂/bicarbonate transporters involved in the CO₂ concentration mechanism which deliver bicarbonate into the cell. The rather recently recognized protein-facilitated transport of CO₂ and/or bicarbonate across membranes adds a fascinating aspect to autotrophic CO₂ metabolism. Currently there are at least five such systems known in cyanobacteria. Independent of the CO₂ assimilation mechanism used by a given organism, CO₂ or bicarbonate has to first enter the cell. Furthermore, the different carboxylating enzymes are specific for either CO₂ or bicarbonate. The rapid interconversion of bicarbonate and CO₂ catalyzed by carbonic anhydrases is at issue as long as carbon flux rates are high enough to make the uncatalyzed interconversion of CO₂/HCO₃[−] rate-limiting. These aspects of CO₂ metabolism have not been addressed in most autotrophs.

Evolutionary Aspect

The question as to whether autotrophy is a primitive trait has been controversial. That is, did heterotrophic life processes evolve after the establishment of autotrophy or did heterotrophic life forms capable of metabolism of low molecular compounds present in the 'primeval soup' precede autotrophy? The speculations, hypotheses, and presentations of the various controversial views on this subject will not be part of this overview.

Mechanisms for CO₂ Assimilation

The assimilation of CO₂ cannot mechanistically be simply a reversal of the oxidation of central metabolic intermediates to CO₂, because (nearly) irreversible steps are usually involved in these oxidative routes. Presently six different pathways for CO₂ assimilation are known. The pathways are listed and described in the order of their discovery. For the figures, each pathway is divided into carboxylation (red), reduction (green), and regeneration (blue) steps. The reductive acetyl-CoA pathway is the only linear, non-cyclic route and, therefore, does not include a regeneration step. The energy requirement, in form of ATP hydrolysis, is not indicated in the figures.

The Reductive Pentose Phosphate Pathway (Calvin-Bassham-Benson Cycle)

In terms of overall CO₂ assimilated, the reductive pentose phosphate pathway for CO₂ fixation is the most important. This is based on the fact that oxygenic phototrophs, like cyanobacteria, algae, and plants, use the reductive pentose phosphate pathway and such organisms generate the majority of the biomass on land and possibly on earth. The primary carboxylating enzyme, ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBisCO), can comprise up to 50% of the soluble cellular protein in organisms using this cycle and is, therefore, considered the most abundant protein on earth. The reason for the high abundance of RuBisCO in the cell is its rather slow turnover number of 3 to 5 molecules per second (for comparison: carbonic anhydrase, albeit one of the fastest enzymes known, turns over one million molecules per second). In addition, various important mechanistic considerations must be accounted for. During catalysis, an enediol of ribulose-1,5-bisphosphate is formed. This intermediate can not only react with CO₂ but also with oxygen. Carboxylation and subsequent hydrolysis of the C₆ carboxylation intermediate produces two molecules of 3-phosphoglycerate whereas in the case of oxygenation, one molecule of 3-phosphoglycerate and one molecule of 2-phosphoglycolate are formed. Two molecules of the C₂ compound 2-phosphoglycolate generate one molecule of 3-phosphoglycerate but one molecule of CO₂ is lost. This process is called photorespiration and requires additional CO₂ to be fixed by RuBisCO in order to compensate for the loss of CO₂ during photorespiration. The ability to discriminate between CO₂ and O₂ as substrates is a characteristic feature of individual RuBisCO enzymes. The so-called specificity factor, which describes the ratio of the efficiency of carboxylation and oxygenation of ribulose-1,5-bisphosphate, varies significantly between RuBisCO enzymes from different sources. There has been great effort in understanding how the two substrates, CO₂ and O₂, are discriminated by RuBisCO with the hope to engineer an enzyme which is more efficient towards the carboxylation reaction.

For every three rounds of the reductive pentose phosphate cycle, one molecule of 3-phosphoglycerate is generated from three molecules of CO₂ (Figure 1). The cycle starts by carboxylation of three molecules of the C₅ compound ribulose-1,5-bisphosphate catalyzed by RuBisCO. Besides one molecule of 3-phosphoglycerate which is taken out of the cycle as the primary CO₂ fixation product, five more molecules of 3-phosphoglycerate are formed. These five C₃ compounds are used to regenerate three C₅ acceptor molecules in form of ribulose-1,5-bisphosphate.

Regeneration starts by the activation of the second carboxyl group of 3-phosphoglycerate to its phosphate-ester, followed by reduction to the level of the aldehyde catalyzed by glyceraldehyde-3-phosphate dehydrogenase. Triosephosphate isomerase catalyzes the equilibrium between glyceraldehyde-3-phosphate and dihydroxyacetone phosphate. The transformation of these five C₃ molecules to two molecules of xylulose-5-phosphate and one molecule of ribose-5-phosphate involves transaldolases and transketolases which catalyze the transfer of C₃- and C₂-fragments between various activated C₄- (erythrose-4-phosphate), C₅- (xylulose-5-phosphate, ribose-5-phosphate), C₆- (fructose-6-phosphate), and C₇- (sedoheptulose-7-phosphate) sugar molecules. Ribose-5-phosphate and xylulose-5-phosphate are converted to ribulose-5-phosphate. Phosphoribulokinase, aside from RuBisCO the second unique enzyme of the reductive pentose phosphate cycle, activates ribulose-5-phosphate to the CO₂ acceptor molecule ribulose-1,5-bisphosphate and the cycle is closed.

Figure 1 The reductive pentose phosphate cycle (Calvin-Bassham-Benson cycle). The primary fixation product of the reductive pentose phosphate cycle is 3-phosphoglycerate.

Four forms of RuBisCO enzymes have been recognized. Members of form I, II, III or IV RuBisCOs have sequence identities of greater than 35% to members of the same class, but less than 30% sequence identity to members of the other classes. Only form I and form II RuBisCO enzymes are involved in autotrophic CO₂ fixation. Form IV RuBisCOs are also referred to as RuBisCO-like proteins, because these enzymes are unable to catalyze carboxylation of ribulose-1,5-bisphosphate and their physiological role is still under investigation. Form III enzymes are bonafide RuBisCOs and occur in some Archaea; again the physiological role of the form III enzymes is not in autotrophic CO₂ fixation. Form I RuBisCO consists of eight small and eight large subunits and it is the form exclusively present in plants, most algae, and cyanobacteria. In the case of other autotrophic bacteria which use the reductive pentose phosphate cycle for autotrophic CO₂ fixation, form I, form II, or both forms I and II of RuBisCO are present. Form II RuBisCO consists only of one type of subunit, similar to the large subunit of form I enzymes.

The Reductive Citric Acid Cycle (Arnon-Buchanan Cycle)

As the name implies, the reductive citric acid cycle for autotrophic CO₂ fixation is the reversal of the oxidative pathway (Krebs cycle, tricarboxylic acid cycle) for conversion of acetyl-CoA to two molecules of CO₂. The reductive citric acid cycle has been discovered and initially studied for the green sulfur bacterium *Chlorobium*. More recently, the thermophilic hydrogen-oxidizing bacterium *Hydrogenobacter thermophilus* has become a focus of studying the enzymology of the reductive citric acid cycle. Steps considered essentially irreversible have to be catalyzed by enzymes different from those of the oxidative citric acid cycle. An outline of the pathway is shown in Figure 2.

The reducing potential of NADH is not sufficient for the reductive carboxylation of succinyl-CoA to 2-oxoglutarate. 2-Oxoglutarate dehydrogenase is, therefore, replaced by 2-oxoglutarate synthase (2-oxoglutarate:ferredoxin oxidoreductase). In addition to using ferredoxin with a more negative redox potential than NADH/NAD⁺ (which makes the reaction reversible), 2-oxoglutarate synthase is also unrelated to the 2-oxoglutarate dehydrogenase enzyme complex. The same is true for pyruvate synthase (involved in the further assimilation of acetyl-CoA via reductive carboxylation of acetyl-CoA to pyruvate) and the pyruvate dehydrogenase complex. 2-Oxoacid dehydrogenases and 2-oxoacid synthases also use different mechanisms. Whereas the 2-oxoacid dehydrogenase complex catalyzes one oxidation step with two electrons transferred, 2-oxoacid synthase catalysis involves two electron transfer steps with a radical intermediate. The later enzyme contains iron-sulfur clusters, which can accept one electron at a time and the enzyme is, therefore, oxygen sensitive. However, the enzyme is found and is functional in some aerobic organisms.

The second (nearly) irreversible step in the oxidative citric acid cycle is the condensation of acetyl-CoA and oxaloacetate to form citrate. The reaction catalyzed by citrate synthase is exergonic, because the activation of the carboxyl group from acetyl-CoA is lost and free CoA released. The ATP- and CoA-dependent cleavage of citrate to acetyl-CoA and oxaloacetate during autotrophic CO₂ fixation by the reductive citric acid cycle, consists of two enzymatic activities: first citrate is activated to citryl-CoA (citryl-phosphate as an intermediate is also involved), which—in a second step—is cleaved into acetyl-CoA and oxaloacetate. For the thermophilic

Figure 2 The reductive citric acid cycle (Arnon-Buchanan cycle). The free intermediates of the pathway for members of the *Aquificaceae*, citryl-CoA and oxalosuccinate, are not shown.

hydrogen-oxidizing bacterium *H. thermophilus* these two activities are confined to two separate enzymes: the first, citryl-CoA synthetase, consists of two different subunits and catalyzes the first step in the citrate cleavage reaction; the enzyme is related to succinyl-CoA synthetase: it requires ATP for CoA transfer and releases adenosine diphosphate (ADP) and inorganic phosphate. A second enzyme, citryl-CoA lyase, cleaves citryl-CoA and forms acetyl-CoA and oxaloacetate. Citryl-CoA lyase is related to citrate synthase. For the green sulfur bacterium *Chlorobium limicola* and *C. tepidum* both steps are catalyzed by a single enzyme. ATP citrate lyase consists of two different subunits; however, these subunits do not correspond directly to the two separate enzymes of *H. thermophilus*. The large subunit of ATP citrate lyase of *Chlorobium* contains the citrate synthase-related citryl-CoA lyase domain as well as an N-terminal part corresponding to the small subunit of the citryl-CoA synthetase enzyme. The second subunit represents the large subunit of citryl-CoA synthetase. Both subunits of the *C. tepidum* enzyme contribute to the active site of ATP citrate lyase. A fusion protein combining the citrate activating and citryl-CoA cleaving domains on a single subunit is found in animals, where ATP citrate lyase plays an important role in fatty acid biosynthesis in the cytosol.

The reversibility of the isocitrate dehydrogenase catalyzing the oxidative decarboxylation of isocitrate to 2-oxoglutarate has been demonstrated for the enzyme from *C. limicola*, even though the equilibrium of the reaction lies on the side of 2-oxoglutarate. In the case of *H. thermophilus* an additional enzyme is required to catalyze the reductive carboxylation of 2-oxoglutarate during CO₂ fixation: 2-oxoglutarate carboxylase is a biotin-containing two-subunit enzyme requiring ATP to form oxalosuccinate (and ADP + P_i) from 2-oxoglutarate and CO₂ (or more likely: bicarbonate). 2-Oxoglutarate carboxylase (formerly named: carboxylating factor for isocitrate dehydrogenase or CFI) is related to pyruvate carboxylase, the enzyme which allows conversion of the C₃-compound pyruvate to the C₄-compound oxaloacetate for the replenishment of the citric acid cycle. A second protein from *H. thermophilus* with almost 50% sequence identity to isocitrate dehydrogenase from *Escherichia coli* has been named oxalosuccinate reductase to indicate its specific role in autotrophic CO₂ fixation. The reductive carboxylation of 2-oxoglutarate to isocitrate by *H. thermophilus* is, therefore, catalyzed by two enzymes: 2-oxoglutarate carboxylase and oxalosuccinate reductase.

The membrane-bound succinate dehydrogenase complex is replaced by soluble fumarate reductase in the reductive citric acid cycle. Even though, depending on the reducing potential of the electron donor, the reduction of fumarate to succinate could be used in energy conservation (fumarate respiration is coupled to the generation of an electrochemical gradient), this has not been observed for autotrophic organisms. An exception may be *Desulfobacter hydrogenophilus*; this sulfate reducer uses the cycle in both directions and fumarate reductase appears to be membrane-bound.

In summary: succinate is formed from the reduction of oxaloacetate and is then activated to its CoA-ester (Figure 2). Two, mechanistically completely different, reductive carboxylation steps follow and isocitrate is formed from succinyl-CoA and two molecules of CO₂. Oxaloacetate is regenerated and acetyl-CoA released as the primary CO₂ fixation product. The last step is brought about by an ATP-dependent citrate cleavage system, which is viewed as the key reaction (sequence) in the reductive citric acid cycle.

The Reductive Acetyl-CoA Pathway (Wood-Ljungdahl Pathway)

The reductive acetyl-CoA pathway is the only linear (non-cyclic) pathway for CO₂ fixation. The pathway is linear because acetyl-CoA, the primary CO₂ fixation product is formed from the direct but independent reduction of two CO₂ molecules—one to the level of a carbonyl-, the other to the level of a methyl group (Figure 3). Therefore regeneration of a primary CO₂ acceptor molecule is not required.

Figure 3 The reductive acetyl-CoA pathway (Wood-Ljungdahl pathway). Due to its metal centers, the key enzyme of the pathway, acetyl-CoA synthase/carbon monoxide dehydrogenase, is extremely oxygen sensitive. ◇ represents a C₁ carrier.

One molecule of CO₂ is reduced to an enzyme-bound carbonyl group. This one-step reduction is catalyzed by an enzyme formerly named carbon monoxide dehydrogenase due to this initially observed activity. The same enzyme, however, also impressively catalyzes carbon-carbon bond formation between this enzyme-bound carbonyl group and an enzyme-bound methyl group, and the carbon sulfur ester bond formation by addition of coenzyme A and was, therefore, renamed acetyl-CoA synthase.

The methyl group is derived from an independent three-step reduction of a second molecule of CO₂. After the first reduction step, catalyzed by formate dehydrogenase, formate is generated as a free intermediate. The subsequent transfer of the formyl group to a C₁ carrier requires the input of energy. Once bound to the C₁ carrier, water is released and the methenyl group reduced in two steps to the methyl group (which corresponds to the oxidation level of methanol). A methyltransferase passes the methyl group from the C₁ carrier on to the corrinoid cofactor of acetyl-CoA synthase, where it will become the methyl group of acetyl-CoA. The nature of the C₁ carriers as well as the electron donors for the reduction steps differ in various organisms using the reductive acetyl-CoA pathway.

Acetogens are eubacteria which form acetate as the main or only product of metabolism. They use the reductive acetyl-CoA pathway for (i) acetyl-CoA synthesis for carbon assimilation from C₁ compounds (including CO₂, carbon monoxide, and formate) as well as for (ii) acetate synthesis and energy conservation from a variety of substrates. Autotrophic growth of acetogens is possible, which means that acetyl-CoA synthesis from CO₂ (with hydrogen as electron donor) requires less than 1 ATP, because only 1 ATP is gained by conversion of acetyl-CoA to acetate. The pathway was discovered for acetogens during heterotrophic growth with glucose, where CO₂ is formed and then used as an electron acceptor (see scheme below). In the case of acetogens the C₁ carrier is tetrahydrofolate.

Methanogens are archaea which form methane as a metabolic product. Many of them also use CO₂ as a carbon source as well as an electron acceptor. For methanogens, reduction of CO₂ results in the formation of methane instead of acetate as for acetogens. The reductive acetyl-CoA pathway is also required for non-autotrophic methanogenic growth with methylated compounds (methanol, methylamines, etc.) for cell carbon biosynthesis. During methanogenic growth on acetate, acetyl-CoA synthase functions in reverse for acetyl-CoA cleavage, the methyl group is reduced to methane, whereas the carbon group is oxidized to CO₂. For archaeal methanogens different pterin-based C₁ carriers have been described (e.g. methanopterin, sarcinopterin). In addition, formate is not a free intermediate of the pathway, but instead reduction of CO₂ in the methyl branch of the pathway leads to formyl-methanofuran. The formyl group is subsequently transferred to the pterin-based C₁ carrier and further reduced to the methyl group.

Some sulfate reducers also use the reductive acetyl-CoA pathway for CO₂ assimilation. The same pathway is used in reverse during growth on acetate; acetate is oxidized completely to CO₂ and the electrons are transferred to sulfate (and hydrogen sulfide is formed).

The 3-Hydroxypropionate/Malyl-CoA Bicycle (Holo-Fuchs Bicycle)

The primary carboxylating enzymes of the 3-hydroxypropionate/malyl-CoA bicycle are acetyl-CoA and propionyl-CoA carboxylase. These biotin-dependent enzymes require ATP for catalysis (forming ADP and inorganic phosphate) and use bicarbonate as the inorganic carbon species instead of CO₂.

Carboxylation of acetyl-CoA forms malonyl-CoA. The activated carboxyl group of malonyl-CoA is reduced completely to form the methyl group of propionyl-CoA. This conversion formally requires five enzymatic reactions: malonyl-CoA reduction to malonate semialdehyde, malonate semialdehyde reduction to 3-hydroxypropionate, activation of 3-hydroxypropionate to its CoA-ester, dehydration of 3-hydroxypropionyl-CoA to acrylyl-CoA, and finally reduction of acrylyl-CoA to propionyl-CoA. Amazingly, for *C. aurantiacus* these steps are catalyzed by only two proteins. Malonyl-CoA reductase is an unusual protein with only limited sequence identity (and only over a short stretch of the protein) to short chain alcohol dehydrogenases related to FabG (3-ketoacyl-(acyl-carrier-protein) reductase). Malonyl-CoA reductase catalyzes the two-step reductive conversion of malonyl-CoA to 3-hydroxypropionate using NADPH as the source for reducing equivalents. Propionyl-CoA synthase is a fusion protein containing three functional domains: an acyl-CoA synthetase domain responsible for the activation of 3-hydroxypropionate to its CoA-ester, an enoyl-CoA reductase domain eliminating water from 3-hydroxypropionyl-CoA thereby forming acrylyl-CoA, and an enoyl-CoA reductase domain reducing acrylyl-CoA to propionyl-CoA using NADPH as the source for reducing equivalents.

Carboxylation of propionyl-CoA forms (2S)-methylmalonyl-CoA. Carbon skeleton rearrangement involves methylmalonyl-CoA epimerase and (2R)-methylmalonyl-CoA mutase and yields succinyl-CoA. In the 3-hydroxypropionate/malyl-CoA bicycle, succinyl-CoA is oxidatively converted to L-malyl-CoA (therefore the name of the pathway) involving enzymes of the citric acid cycle as well as succinyl-CoA:malate CoA transferase (Figure 4). L-Malyl-CoA lyase, a key enzyme of this pathway, regenerates acetyl-CoA and yields glyoxylate as the primary CO₂ fixation product. Glyoxylate has to be converted to central biosynthetic intermediate for further assimilation. The assimilation of glyoxylate for *C. aurantiacus* requires a second cycle. Propionyl-CoA is formed by carboxylation of acetyl-CoA and reductive conversion of malonyl-CoA via 3-hydroxypropionate as described

Figure 4 The 3-hydroxypropionate/malyl-CoA bicycle (Holo-Fuchs bicycle). The primary fixation product of the first cycle is glyoxylate which is further converted to pyruvate in the second cycle. The first half of both cycles is the same.

(Figure 4). Glyoxylate then condenses with propionyl-CoA to form erythro- β -methylmalonyl-CoA, a step which is catalyzed by the L-malyl-CoA lyase, the final enzyme of the first cycle. β -Methylmalonyl-CoA is dehydrated to mesaconyl-C1-CoA (2-methylfumaryl-CoA) and a CoA transferase transfers the CoA moiety from one end of mesaconyl-C1-CoA to the other side of the molecule, forming mesaconyl-C4-CoA (3-methylfumaryl-CoA). Hydration of mesaconyl-C4-CoA yields (S)-citramalyl-CoA,

which is cleaved into acetyl-CoA and pyruvate. Therefore, in the second cycle, propionyl-CoA and glyoxylate have been converted to acetyl-CoA (from which propionyl-CoA is formed) and the CO₂ fixation product pyruvate, a central intermediate from which cell carbon biosynthesis can proceed by conventional reactions.

The 3-Hydroxypropionate/4-Hydroxybutyrate Cycle

The 3-hydroxypropionate/4-hydroxybutyrate assimilation pathway shares intermediates with the 3-hydroxypropionate/malyl-CoA bicycle—most notably the intermediate 3-hydroxypropionate (Figure 5). The enzymes involved in the transformation of these common intermediates, however, are different for the two pathways. In the case of *M. sedula*, using the 3-hydroxypropionate/4-hydroxybutyrate cycle, five individual enzymes are required for the reductive conversion of malonyl-CoA to propionyl-CoA compared to only two (fusion) proteins for *C. aurantiacus*. Furthermore, NADPH-dependent malonyl-CoA reductase of *M. sedula* (catalyzing only a one-step reduction of malonyl-CoA to malonate semialdehyde and succinyl-CoA to succinate semialdehyde) is unrelated to the enzyme from *C. aurantiacus* (catalyzing a two-step reduction of malonyl-CoA to 3-hydroxypropionate). Instead, malonyl-CoA reductase from *M. sedula* is homologous to aspartate semialdehyde dehydrogenases. Likewise, acrylyl-CoA reductase of *M. sedula* shares very limited sequence identity (centered around a conserved NADPH-binding site) with the enoyl-CoA reductase domain of the trifunctional propionyl-CoA synthase from *C. aurantiacus* catalyzing the same reaction. Carboxylation of propionyl-CoA is catalyzed by a biotin/ATP-dependent and bifunctional acetyl-CoA/propionyl-CoA carboxylase. Succinyl-CoA is formed by carbon skeleton rearrangement of (2R)-methylmalonyl-CoA.

From here on out the 3-hydroxypropionate/4-hydroxybutyrate cycle differs from the 3-hydroxypropionate/malyl-CoA bicycle. The reductive conversion of succinyl-CoA to two molecules of acetyl-CoA regenerates the primary CO₂ fixation acceptor molecule, acetyl-CoA; the second acetyl-CoA molecule represents the primary CO₂ fixation product (Figure 5). This reaction sequence involves several interesting reactions: succinyl-CoA is reduced with NADPH to succinate semialdehyde, a reaction catalyzed by the same enzyme that reduces malonyl-CoA to malonyl-CoA semialdehyde. Succinate semialdehyde is further reduced to the characteristic intermediate 4-hydroxybutyrate (therefore the name of the pathway) which is activated to its CoA-ester. The 3-hydroxypropionate/4-hydroxybutyrate cycle was discovered after detection of 4-hydroxybutyryl-CoA dehydratase activity in cell extracts of autotrophically-grown *M. sedula*. The enzyme catalyzes the challenging elimination of water from an activated 4-hydroxyacid by a and had been discovered and previously only been described during fermentation by certain clostridia. 4-Hydroxybutyryl-CoA dehydratase yields crotonyl-CoA. The oxidative conversion of crotonyl-CoA to two molecules of acetyl-CoA via 3-hydroxybutyrate and acetoacetyl-CoA involves reactions known from other common metabolic routes.

Figure 5 The 3-hydroxypropionate/4-hydroxybutyrate cycle. Although the reaction sequence of the first half of the cycle is shared with the 3-hydroxypropionate/malyl-CoA bicycle, most enzymes of the reductive conversion of malonyl-CoA to propionyl-CoA are unrelated in the two pathways, as studied for *Chloroflexus aurantiacus* (3-hydroxypropionate/malyl-CoA bicycle) and *Metallosphaera sedula* (3-hydroxypropionate/4-hydroxybutyrate cycle).

The Dicarboxylate/4-Hydroxybutyrate Cycle

The dicarboxylate/4-hydroxybutyrate and 3-hydroxypropionate/4-hydroxybutyrate cycles have in common the reaction sequences regenerating acetyl-CoA from succinyl-CoA and forming a second acetyl-CoA molecule as the CO₂ fixation product. Therefore, 4-hydroxybutyrate is also the characteristic intermediate of this CO₂ fixation pathway and 4-hydroxybutyryl-CoA dehydratase, is also the key enzyme.

The formation from succinyl-CoA from acetyl-CoA and two molecules of inorganic carbon, however, differ between the two 4-hydroxybutyrate cycles and both employ different carboxylases (Figure 4 and 5). In the dicarboxylate/4-hydroxybutyrate cycle (Figure 5), acetyl-CoA is reductively carboxylated by pyruvate:ferredoxin oxidoreductase (=pyruvate synthase). Pyruvate is phosphorylated by pyruvate water dikinase. The product, phosphoenolpyruvate (PEP), is carboxylated by PEP carboxylase to form oxaloacetate. Reactions of the reductive citric acid cycle convert oxaloacetate to succinyl-CoA. Therefore, in the dicarboxylate/4-hydroxypropionate cycle, one molecule of acetyl-CoA is formed from one molecule of CO₂ and one molecule of bicarbonate. Parts of the first half of the cycle are also used for synthesis of pyruvate (or succinyl-CoA) from acetyl-CoA, CO₂ (and bicarbonate).

Other CO₂ Assimilation Pathways

It is very likely that other mechanisms for CO₂ fixation will be described, for example for bacteria and archaea which will be discovered in the future. So far a considerable number of extremophiles have turn out to be autotrophs using chemical energy (mainly anaerobic respiration) for growth. The description of the 3-hydroxypropionate/4-hydroxybutyrate cycle also shows that parts of one CO₂ fixation pathway may be combined with other reaction sequences to create a new cycle. Also, variations of the known six CO₂ assimilation pathways are expected to exist.

Assessment of the Distribution of the Different Pathways

Key Enzymes

Key enzymes of pathways catalyze reactions yielding or using unique intermediates in metabolism that are characteristic for that particular pathway. Key enzymes can, therefore, be used as markers and their detection provide an excellent indication for the presence of an entire reaction sequence involving other enzymes that are shared with more common pathways of central carbon metabolism.

The key enzymes of the reductive pentose phosphate cycle are phosphoribulokinase and RuBisCO (Figure 1). Phosphoribulokinase catalyzes the ATP-dependent activation of ribulose-5-phosphate to ribulose-1,5-bisphosphate, which is the primary CO₂ acceptor molecule of the reductive pentose phosphate cycle. RuBisCO, of course, is the carboxylating enzyme that uses ribulose-1,5-bisphosphate as its substrate, forming two molecules of 3-phosphoglycerate.

The key reaction sequence of the reductive citric acid cycle is the ATP-dependent conversion of citrate to acetyl-CoA and oxaloacetate (Figure 2). This reaction is catalyzed by ATP citrate lyase or two enzymes: citryl-CoA lyase and citryl-CoA synthetase, depending on the organism. Enzymes of both ATP-dependent citrate cleavage systems are related. In addition, pyruvate and 2-oxoglutarate synthase are required for the reductive carboxylation of acetyl-CoA and succinyl-CoA.

The key enzyme of the reductive acetyl-CoA pathway is acetyl-CoA synthase/carbon monoxide dehydrogenase, which catalyzes the reduction of CO₂ to an enzyme-bound CO intermediate (Figure 3). The enzyme also catalyzes formation of acetyl-CoA from the enzyme-bound carbonyl group, an enzyme-bound methyl group, and coenzyme A. In addition, pyruvate synthase is required for the functioning of the reductive acetyl-CoA pathway for further assimilation of the primary CO₂ fixation product acetyl-CoA.

There are several reaction sequences which appear to be unique but also common to the 3-hydroxypropionate/malyl-CoA bicycle and 3-hydroxypropionate/4-hydroxybutyrate cycle (Figure 4 and 5). Therefore, the enzymes involved in these reactions can all be referred to as key enzymes. The two-step reduction of malonyl-CoA leads to the formation of 3-hydroxypropionate. This characteristic intermediate is further reduced to propionyl-CoA via acrylyl-CoA. Specifically for the 3-hydroxypropionate/malyl-CoA bicycle, L-malyl-CoA lyase is the key enzyme, whereas 4-hydroxybutyryl-CoA dehydratase is characteristic for the 3-hydroxypropionate/4-hydroxybutyrate cycle. 4-Hydroxybutyryl-CoA dehydratase is also the characteristic enzyme for the dicarboxylate/4-hydroxybutyrate cycle (Figure 6); however, organisms using this CO₂ fixation pathway lack the biotin-dependent carboxylase as well as a malonyl-CoA reductase.

Detection of Key Enzymes

The detection of key enzymatic activities in cell extracts of autotrophically grown cells of a particular organism is a prerequisite to assign a particular CO₂ fixation pathway used by a certain species. The specific activity of the key enzyme must be high enough to account for the doubling time of the organism during autotrophic growth. It is likely that the activity is down-regulated during growth on an organic substrate (heterotrophic growth) instead of CO₂ (autotrophic growth). Regulation of an activity in facultative autotrophs in response to growth substrate is an excellent indication of the enzyme's proposed role in a particular pathway. In some instances it is also possible to follow an entire reaction sequence using cell extracts. Similarly, short-term labeling studies with ¹⁴CO₂ or other ¹⁴C-labeled (suspected) intermediates and cell extracts or cell suspensions have been found to be extremely helpful.

Figure 6 The dicarboxylate/4-hydroxybutyrate cycle. The second half of the cycle is shared with the 3-hydroxypropionate/4-hydroxybutyrate cycle. The first half of the cycle is used by other organisms to assimilate acetyl-CoA.

As confirmation of a particular CO₂ fixation mechanism used by a given organism, activities of key enzymes of alternate CO₂ assimilation pathways are expected to be absent.

With the advent of complete genome sequences there is the temptation to assign a specific mechanism for CO₂ fixation of an autotrophic organism based on genomic analysis alone. Furthermore, one may even wish to uncover the prevailing CO₂ fixation pathway in a particular habitat, analyzing sequences derived from entire communities (metagenomics). The assignment of the gene encoding for the key enzyme of a pathway is not sufficient. Candidates for all genes involved in the pathway must be assigned. It is not uncommon to find several enzymes of a pathway encoded by genes that are clustered on the genome. In order to confirm the proposed role of an assigned gene, it is usually cloned, heterologously expressed, and the recombinant enzyme analyzed for its predicted activity. In some cases, enzymes catalyzing subsequent reactions in a pathway are even fused; for example, propionyl-CoA synthase from *C. aurantiacus* of the 3-hydroxypropionate/malyl-CoA bicycle consists of three domains corresponding to enzymes catalyzing the activation of 3-hydroxypropionate to its CoA-ester, dehydration of 3-hydroxypropionyl-CoA, and reduction of acrylyl-CoA to propionyl-CoA. For *Roseiflexus* species the gene encoding propionyl-CoA synthase is found clustered with genes encoding malonyl-CoA reductase and the subunits of acetyl-CoA/propionyl-CoA carboxylase; other genes encoding for enzymes required for the 3-hydroxypropionate/malyl-CoA bicycle are found elsewhere on the genome. It, therefore seems clear that *Roseiflexus* use the 3-hydroxypropionate/malyl-CoA bicycle for CO₂ assimilation. This, however, was surprising because isolates of *Roseiflexus* species, which are filamentous anoxygenic phototrophic bacteria related to *C. aurantiacus* (83% sequence identity on the 16S rRNA level), had not been shown to grow autotrophically. It is possible that *Roseiflexus* species might use the 3-hydroxypropionate/malyl-CoA bicycle to fix CO₂, while coassimilating organic carbon compounds at the same time (mixotrophic growth).

More often than not, the assignment of a particular CO₂ assimilation mechanism or the prediction of the capability of a given organism to grow autotrophically, based on genomic data alone, is not straightforward. The following situations are often encountered:

1. Specific genes can be assigned but are not involved in autotrophic growth. A good example is the presence of a gene encoding RuBisCO in many methanogenic archaea. The enzyme represents a form III RuBisCO and is not involved in autotrophic CO₂ assimilation. These organisms use the reductive acetyl-CoA pathway for CO₂ fixation. ATP citrate lyases are present in a variety of organisms including mammals and play a role in fatty acid biosynthesis. Genes for 2-oxoacid synthases (2-oxoacid:ferredoxin oxidoreductase) are found in many genomes, especially in genomes of strict anaerobic—and at the same time strict heterotrophic—bacteria. The reductive acetyl-CoA pathway and the reductive citric acid cycle can be used exclusively in reverse by some organisms for acetyl-CoA oxidation during heterotrophic growth. 4-Hydroxybutyryl-CoA dehydratase one of the key enzymes of the 3-hydroxypropionate/4-hydroxybutyrate cycle and dicarboxylate/4-hydroxybutyrate cycle was first discovered in *Clostridium aminobutyricum* where it is involved in fermentation.

2. Not all (required) genes of a CO₂ assimilation pathway can be assigned. Although ATP citrate lyase activity (albeit low) was detected in cell extracts of *Thermoproteus tenax* and *Magnetococcus* sp. MC-1 and additional evidence was presented for the functioning of the reductive citric acid cycle in these bacteria, a corresponding gene for ATP citrate lyase is absent in the completed genome sequences. It is not clear, if another CO₂ assimilation pathway is operating in these organisms or if the enzyme catalyzing the cleavage of citrate is unrelated to ATP citrate lyase or citryl-CoA lyase. An alternate mechanism for citrate conversion to acetyl-CoA and oxaloacetate has been proposed but experimental evidence is missing. In case of the 3-hydroxypropionate/malyl-CoA bicycle, the conversion of malonyl-CoA to propionyl-CoA involves different and in some instances completely unrelated enzymes compared to the 3-hydroxypropionate/4-hydroxybutyrate cycle. Catalysis of identical reactions by unrelated enzymes (convergent evolution) is not unexpected, especially with members of general enzyme classes, like dehydrogenases, hydratases, acyl-CoA synthetases, etc.
3. Genes specific for several pathways appear to be present. The genome of *Archaeoglobus fulgidus* harbors genes encoding proteins related to RuBisCO (form III), acetyl-CoA synthase/carbon monoxide dehydrogenase, and 4-hydroxybutyryl-CoA dehydratase. The reductive acetyl-CoA pathway is thought to function as the autotrophic CO₂ assimilation pathway.

Confirmation (or refutation) of a proposed pathway for CO₂ assimilation is possible by long-term ¹³C-labeling studies as discussed below. This, however, requires rather robust growth of an isolated organism. In case of bacteria and archaea not amenable for mass cultivation, additional evidence might be obtained by studying ¹³C isotope contents in habitats or microbial consortia which might be indicative for the presence of a specific CO₂ assimilation pathway.

Qualitative Assessment (¹³C Isotopic Depletion)

Differences in stable ¹³C isotope content (relative to ¹²C) between inorganic carbon and organic matter synthesized from CO₂ by autotrophs may be used to suggest a specific mechanism for CO₂ fixation. For example, the depletion of ¹³C in organic matter relative to CO₂ from which the carbon was derived via the reductive pentose phosphate pathway is due to the preference of RuBisCO for ¹²CO₂ relative to ¹³CO₂. An isotopic signature of sedimentary organic matter of −20 to −30‰ is typical for CO₂ assimilation via the reductive pentose phosphate pathway. In contrast CO₂ fixation via the reductive citric acid cycle only leads to a depletion of −2 to −12‰. For the 3-hydroxypropionate/malyl-CoA bicycle a depletion value of −13‰ has been reported. The depletion of ¹³C carbon of organic matter formed by the reductive acetyl-CoA pathway relative to the ¹³CO₂ assimilated is greater than −30‰; for the 4-hydroxybutyrate cycles these values are much closer to zero.

The analysis of stable carbon isotopes can provide insights into carbon fixation mechanisms used (and the type of organisms involved) in a given habitat. This concept has been applied to microbial mats present in the effluent of sulfur-containing hot springs. The ¹³C isotope content of organic matter of mats close to the source pool was diagnostic for the 3-hydroxypropionate/malyl-CoA bicycle, consistent with the fact that those mats were constructed mainly by *Chloroflexus* species. Mats further downstream formed by both cyanobacteria and *Chloroflexus* had a more typical reductive pentose phosphate cycle signature. However, compound-specific isotope analysis of unique lipids of *Chloroflexus* pointed mainly to CO₂ assimilation (via the 3-hydroxypropionate/malyl-CoA bicycle) in addition to some cross-feeding of photosynthetic products from cyanobacteria by *Chloroflexus*.

Qualitative Assessment (Long-term *in vivo* ¹³C-tracer Labeling Studies)

A very elegant method has been introduced to analyze the specific fate of fixed CO₂ into specific positions of central precursor metabolites, reflecting the mechanism of CO₂ assimilation in a given autotrophic organism. Limited amounts of differentially ¹³C-labeled intermediates of the proposed CO₂ fixation pathway are added as tracers to cultures growing autotrophically. After several generation times, the cells are harvested and major cell constituents are isolated. The ¹³C-labeling patterns of several building blocks (sugars, amino acids, nucleotides, etc.) are determined by quantitative nuclear magnetic resonance (NMR) spectroscopy. Based on known biosynthetic pathways, ¹³C-labeling patterns of central metabolic metabolites are retraced. It is important to note that the labeling pattern of a particular central metabolite is determined multiple times, because all the different building blocks are derived from one or several of these central metabolites. Therefore, variations in specific biosynthetic pathways in a particular organism can be accounted for. These results are compared with predicted labeling patterns based on the proposed CO₂ assimilation pathway which either leads to the confirmation or falsification of the suggested pathway.

Distribution and Physiological Restraints

There is no clear distribution of the different autotrophic CO₂ fixation pathways according to phylogenetic groups (Table 1). However, *Archaea* as well as strict anaerobic bacteria appear to use a mechanism for CO₂ fixation distinct from the reductive pentose phosphate cycle. The 3-hydroxypropionate cycles do not seem to be used by strict anaerobes.

The diversity of different pathways for the assimilation of inorganic carbon is at first unexpected. However, an alternate way to fix CO₂, other than the very energy-demanding reductive pentose phosphate pathway, was expected for organisms that are only able to gain rather limited energy through their metabolism (e.g. strict anaerobic microorganisms). At the same time, an anaerobic version for CO₂ fixation would not be feasible for aerobic organisms, because some of the enzyme involved in the reductive citric acid cycle

Table 1 Distribution of the different pathways for CO₂ fixation among various phylogenetic and physiological relevant groups

CO ₂ assimilation pathway	Phylogenetic groups	Physiological groups	Examples
Reductive pentose phosphate pathway (Calvin-Bassham-Benson cycle)	chloroplasts cyanobacteria purple non-sulfur bacteria, purple sulfur bacteria, α -/ γ -proteobacteria, etc.	oxygenic phototrophs, anoxygenic phototrophs, hydrogen-/sulfur-/ ammonium-oxidizers nitrate reducers	plants, algae, <i>Synechococcus</i> sp., <i>Rhodobacter sphaeroides</i> , <i>Rhodospirillum rubrum</i> , <i>Ralstonia eutropha</i> , <i>Xanthobacter autrophicus</i> , <i>Thiomicrospira crunogena</i>
Reductive citric acid cycle (Arnon-Buchanan cycle)	green sulfur bacteria, δ -/ ϵ -proteobacteria, <i>Desulfobacteriaceae</i> , <i>Aquificaceae</i> , etc.	anoxygenic phototrophs, hydrogen-/sulfur oxidizers, sulfur reducers, sulfate reducers	<i>Chlorobium tepidum</i> , <i>Hydrogenobacter thermophilus</i> , <i>Desulfobacter hydrogenophilus</i> , <i>Sulflurimonas denitrificans</i>
Reductive acetyl-CoA pathway (Wood-Ljungdahl pathway)	<i>Desulfobacteriaceae</i> , Methanobacteria, etc.	homoacetogens, methanogens sulfate reducers	<i>Moorella thermoacetica</i> , <i>Methanothermobacter thermoautotrophicus</i> , <i>Desulfobacterium autotrophicum</i> , <i>Ferroglobus placidus</i>
3-Hydroxypropionate/malyl-CoA bicycle	green non-sulfur, bacteria, Sulfolobales	anoxygenic phototrophs,	<i>Chloroflexus aurantiacus</i>
3-Hydroxypropionate/ 4-hydroxybutyrate cycle	Thermoproteales, Desulfococcales	thermophilic hydrogen-/ sulfur- oxidizers	<i>Metallosphaera sedula</i> , <i>Stygiolobus azoricus</i>
Dicarboxylate/ 4-hydroxybutyrate cycle			<i>Ignicoccus hospitalis</i> , <i>Pyrocolobus fumari</i>
unknown			e.g., <i>Pyrodictium</i>

and especially the reductive acetyl-CoA pathway are oxygen-sensitive. (The reductive citric acid cycle, however, is also used by some microaerophilic and even aerobic bacteria with high O₂ respirations rates). In addition to these two 'anaerobic' versions (reductive acetyl-CoA pathway/reductive citric acid cycle), at least three versions of high-energy-demanding CO₂ assimilation pathways are now known: the reductive pentose phosphate cycle and the 3-hydroxypropionate cycles. The 3-hydroxypropionate/4-hydroxybutyrate cycle uses 4-hydroxybutyryl-CoA dehydratase, an enzyme containing oxygen labile iron-sulfur clusters and so far the pathway has been described for microaerophiles and may also occur in strict anaerobes. Clearly, the presence of oxygen demands adaptation of the CO₂ mechanism employed; this is mainly due to the fact, that the use of reducing equivalents with low redox potentials makes assimilation of CO₂ more energy efficient, reversible, but at the same time prevents their use in the presence of high oxygen tensions.

So why do even related organisms, for example different species of sulfur-reducers of the Desulfobacterales, use one 'anaerobic' version for CO₂ fixation over the other (Table 1)? Why is the 3-hydroxypropionate/malyl-CoA bicycle generally used by anoxygenic phototrophic green nonsulfur bacteria and the reductive pentose phosphate cycle by phototrophic purple nonsulfur bacteria capable of anaerobic CO₂ fixation? Clearly, there appear to be additional constraints for a particular microorganism to use one pathway rather than another, which are not understood at this point.

The differences between the six (and there might be more) CO₂ assimilation pathways extends beyond the energy requirements and type of electron carriers used. As a matter of fact, those two variables can even differ for the same CO₂ fixation mechanism; for example, the reductive citric acid cycle requires up to two more ATPs to synthesize one molecule of acetyl-CoA from two molecules of CO₂ in the case of *H. thermophilus* compared to *Desulfobacter hydrogenophilus*. In addition, different electron carriers for the reductive acetyl-CoA pathway are used by methanogens and acetogens. Additional differences between the various CO₂ assimilation pathways are also: (a) the requirement for specific cofactors and metals, (b) the type of inorganic carbon species (CO₂ or bicarbonate) assimilated, and (c) and perhaps most importantly, the type of metabolic intermediates through which the carbon passes.

It has been speculated that the 3-hydroxypropionate cycles allow for the simultaneous assimilation of fermentative products, such as acetate or propionate. Likewise the reductive acetyl-CoA pathway can be used for (co)assimilation of C₁-compounds (carbon monoxide, formaldehyde, formate, methanol, and methyl groups of methylamines). The latter pathway is also reversible and is used for acetate fermentation by methanogens or even some acetogens, provided that the hydrogen partial pressure is kept low. The assimilation of organic compounds and inorganic carbon by parts of the same pathway then would allow for metabolic flexibility such that some or all of the same enzymes may be used for autotrophic, heterotrophic or mixotrophic growth. It would be very exciting then, if there were examples of organisms capable of using different CO₂ fixation pathways depending on overall carbon availability. Even for purple nonsulfur bacteria (which use the reductive pentose phosphate cycle) where autotrophic and heterotrophic growth appeared to be clearly separated at first, RuBisCO has been shown to act in redox-balancing by using CO₂ as an electron sink during photoheterotrophic growth on various organic carbon compounds. The unique integration of a particular CO₂ assimilation pathway into the overall carbon metabolism of an organism is therefore an exciting field for further study.

Quantitative Assessment

In terms of total biomass generated, the reductive pentose phosphate pathway is the most important CO₂ assimilation pathway, because it is used by land plants, algae and cyanobacteria, which are also responsible for maintaining the oxygen level in the atmosphere. With regard to bacterial CO₂ fixation, the contribution of the individual pathways appears to be much more difficult to assess. However, considering the ubiquitous occurrence of cyanobacteria, again there is no doubt that the reductive pentose phosphate pathway contributes the most. Even more importantly, oxygenic photosynthesis allows the synthesis of extensive biomass.

In specific habitats, for example anaerobic or hypothermal, one particular pathway – other than the reductive pentose phosphate cycle might become dominant. Recent studies, for example, point to the prevalence of the reductive citric acid cycle as the main CO₂ assimilation pathway at hypothermal vents. This pathway is employed by proteobacteria of the ϵ -group, like *Sulfurimonas denitrificans* or an epibiont of the marine worm *Alvinella pompejana*, contributing significantly to primary production at such sites. Also, it has been suggested that the sulfide-oxidizing uncultured endosymbiont belonging to the γ -proteobacteria, which supplies the deep-sea tube worm *Riftia pachyptila* with fixed carbon, uses the reductive citric acid cycle for CO₂ assimilation, although RuBisCo is also present in the organism and might be used under conditions where the energy supply is plentiful.

Regulation

Facultative autotrophic organisms are able to also use organic substrates as their carbon source if these are available. Organic carbon compounds usually become the preferred carbon source over CO₂, because less energy and possibly no exogenous electrons are required for their assimilation. Therefore, the enzymes needed for autotrophic CO₂ fixation are under tight regulation in these facultative autotrophs. Even during mixotrophic growth, when CO₂ and organic carbon are assimilated simultaneously, flow through the CO₂ fixation pathway must be controlled and this is depended on the availability of energy and reducing equivalents.

It is clear that the type of regulation depends on the organism studied as well as the CO₂ fixation mechanism employed. The reductive citric acid cycle and the reductive acetyl-CoA pathways may be used in reverse for the oxidation of acetyl-CoA by some bacteria (sulfate reducers, acetogenic/methanogenic consortia) and even the same enzymes might be involved. Such a scenario would then make posttranslational regulation most likely under those conditions. However, this has not been established at this time.

Limitations to study regulation of the 3-hydroxypropionate/malyl-CoA bicycle, the 3-hydroxypropionate/4-hydroxybutyrate cycle and the dicarboxylate/4-hydroxybutyrate cycle at present revolve around the lack of genetic tools for organisms using these pathways for CO₂ assimilation. The activities of key enzymes of the 3-hydroxypropionate/malyl-CoA bicycle are up-regulated during autotrophic versus heterotrophic growth. Of particular interest is the branch point at the level of malonyl-CoA; this C₃ compound is either used for fatty acid synthesis or reduced to 3-hydroxypropionate for further conversion to other central precursor metabolites. The pathway is considered irreversible, making acrylyl-CoA reduction to propionyl-CoA the committed step of the pathway.

Regulation of the reductive pentose phosphate cycle is, therefore, the only CO₂ assimilation pathway studied in some detail. Here the current state of knowledge on the regulation of CO₂ fixation by purple non-sulfur bacteria is briefly discussed. Purple non-sulfur bacteria represent an excellent group of organisms to study carbon metabolism and the molecular basis for its regulation: their enormous metabolic versatility allows them to grow under a variety of different growth modes (anaerobically in the light, aerobically in the dark and even fermentatively that is anaerobically in the dark) using many organic substrates as their carbon source as well as CO₂. In addition, the complete genome sequences of several purple non-sulfur bacteria (*Rhodobacter sphaeroides*, *Rb. capsulatus*, *Rhodospirillum rubrum*, and *Rhodopseudomonas palustris*) have been determined over the last years and genetic tools are in place.

RuBisCO catalyzes the irreversible carboxylation step in the reductive pentose phosphate cycle and is regulated during autotrophic versus heterotrophic growth. A regulator protein, called CbbR (for Calvin-Benson-Bassham cycle regulator), controls the transcription of genes encoding RuBisCO enzymes in all purple non-sulfur bacteria studied and also other bacteria, including non-phototrophic bacteria. As mentioned before, some purple non-sulfur bacteria produce two forms of RuBisCO (e.g. *Rb. sphaeroides*) and the genes encoding both forms I and II are regulated by CbbR. The genes for either form are found in different gene clusters or operons located on distinct chromosomal loci where they are cotranscribed (and coregulated) with additional genes, especially those that encode enzymes required for the regeneration of ribulose-1,5-bisphosphate, the substrate of RuBisCO. CbbR is a transcriptional regulator belongs to a class of DNA-binding proteins (LysR-type regulators) that often require the binding of small molecules effectors or coinducers in order to be active in controlling transcription. It is likely that CbbR binds a metabolite which is present under conditions where CO₂ fixation is desirable but the nature of various positive and negative effector molecules might be different for different bacteria. For *Rp. palustris*, an additional level of regulatory control is added: a three protein two-component system that is thought to influence the activity of CbbR, the details of this are only beginning to be understood. Oxygen is also sensed and the signal transmitted through the two-component RegAB (also called PrrAB) system in *Rhodobacter*. Furthermore there is differential regulation of the form I and II enzymes and their cognate operons, suggesting additional signals or regulatory elements. Finally, there is also indication of posttranslational regulation and modulation of activity of RuBisCO by certain metabolites, among them the substrate ribulose-1,5-bisphosphate, which is thought to bind tightly to the active site of form I enzymes. Studies on the overall regulation of RuBisCO have already revealed the need for CO₂ fixation by RuBisCO, not only during autotrophic CO₂ assimilation, but also for balancing the redox state of the cell during photoheterotrophic growth.

General Characteristics

Bacillus thuringiensis (Bt) is a member of the *Bacillus cereus* group that also includes *B. cereus*, *B. anthracis* and *B. mycoides* (Helgason et al., 2000). The feature that distinguishes Bt from the other members of the *Bacillus cereus* group is its entomopathogen properties. Bt produces insecticidal proteins (Cry and Cyt toxins) during sporulation phase as parasporal crystals. These crystals are predominantly comprised of one or more proteins, also called δ -endotoxins or Cry proteins. These toxins are highly specific to their target insect, are innocuous to humans, vertebrates and plants, and are completely biodegradable. Therefore, Bt is a viable alternative for the control of insect pests in agriculture and disease vectors of importance in public health.

Numerous Bt strains have been isolated that show activity towards lepidopteran, dipteran or coleopteran insects (Schnepf et al., 1998). In recent years Bt strains active against Hymenoptera, Homoptera, Orthoptera and Mallophaga insect orders and to other non-insect organisms like nematodes, mites and protozoa have been isolated (Crickmore et al., 1998; Wei et al., 2003). The entomopathogenic activity of Bt is mainly due to Cry toxins. One feature that distinguishes Cry proteins is their high specificity for their target insect. More than 300 different *cry* genes have been isolated. This constitutes an important arsenal for the control of a wide variety of insect pests. In this article we will summarize the knowledge on the pathogenic properties of Bt, the mode of action of Cry toxins and their application in agriculture and disease-vector control.

Since the publication of the article *Bacillus thuringiensis*, with Resistance mechanisms, in *Comprehensive Molecular Insect Science* (2005) there have been important developments in the understanding the mode of action of these toxins in different insect orders, in resistance mechanisms and gene discovery. Different recent reviews that revise recent literature regarding gene discovery and toxin evolution (Bravo et al., 2013; Adang et al., 2014), toxin mode of action (Vachon et al., 2012; Pardo-López et al., 2013; Adang et al., 2014), resistance evolution and ways to counter resistance (Bravo and Soberón, 2008; Tabashnik et al., 2013) have been published. Following we highlight the most important developments on *Bacillus thuringiensis* Cry toxins in recent years.

Virulence Factors and the PlcR Regulon

The *B. cereus* group is characterized by its pathogenic capabilities in diverse type of organism as mammals in the case of *B. anthracis* and *B. cereus* or to insects in the case of Bt. The pathological characteristics of the different members of the *B. cereus* group is mainly due to the presence of specific toxin genes that are most of the time encoded by large, self transmissible extrachromosomal plasmids (Schnepf et al., 1998). However, other chromosomal encoded virulence factors contribute to the pathogenic effect of the different members of the *B. cereus* group (Dubois and Dean, 1995; Lereclus et al., 1996; Agaisse et al., 1999; Guttmann and Ellar, 2000). In the case of Bt, it has been known for some time that Bt spores synergies the effect of Cry proteins (Dubois and Dean, 1995). This synergistic effect was shown to be due to the production of several virulence factors, such as α -exotoxins, β -exotoxins, chitinases, phospholipases and enterotoxins (Lereclus et al., 1996; Agaisse et al., 1999; Guttmann and Ellar, 2000).

Mutation of genes encoding some of these virulence factors showed that they contribute to the pathogenicity of Bt to insects (Lereclus et al., 1996; Fedhila et al., 2002). In the case of phosphatidylinositol specific phospholipase C (PI-PLC), the disruption of the structural gene *plcA* diminished the synergistic effects of spores indicating that at least this virulence factor was necessary for an efficient virulence of the bacterium (Lereclus et al., 1996). This is also the case for the *inhA2* gene that codes for a zinc-requiring metalloprotease (Fedhila et al., 2002). The characterization of the mechanism controlling *plcA* gene expression led to the discovery of a pleiotropic transcriptional regulator, PlcR. Mutations in the *plcR* gene abolished *plcA* gene expression and the virulence of the bacterium (Lereclus et al., 1996; Agaisse et al., 1999). A genetic screening of PlcR regulated genes identified several extra cellular virulence factors including a secreted RNase, a S-layer protein, phospholipase C and enterotoxins indicating that the PlcR-regulon

[☆]Change History: Updated by Mario Soberón and Alejandra Bravo

This article is an update of A. Bravo, M. Soberón, S.S. Gill, 6.6 - *Bacillus thuringiensis*: Mechanisms and Use, *Comprehensive Molecular Insect Science*, edited by Lawrence I. Gilbert, Elsevier, 2005, pp. 175–205.

Fig. 1 PlcR regulon in *Bacillus thuringiensis*. Positive (+) and negative (–) regulation in the PlcR regulon.

include a diverse set of virulence factors (Agaïsse et al., 1999). Also, the *inhA2* gene was shown to be under the control of PlcR (Fedhila et al., 2003). A proteome analysis of secreted proteins from *B. cereus* strain ATCC 14,579 showed that disruption of the *plcR* gene reduced the levels at least 56 exported proteins (Gohar et al., 2002). Alignment of the promoter regions of the PlcR-regulated genes identified a 20-nucleotide palindromic sequence (“PlcR box”) that is required for PlcR activation (Agaïsse et al., 1999). Although, several PlcR regulated genes are also present in *B. cereus* and *B. anthracis* (Guttmann and Ellar, 2000), only the *B. cereus* PlcR protein is functionally equivalent to that of Bt since the *B. anthracis plcR* gene is disrupted by a transposon-like sequence indicating that production of virulence factors in *B. anthracis* is blocked or may be different from that of Bt and *B. cereus* (Agaïsse et al., 1999). In fact, expression of a functional PlcR in *B. anthracis* leads to the activation of a large set of genes encoding enzymatic and toxin activities including protease, phospholipase and haemolysis (Mignot et al., 2001).

PlcR regulated genes are expressed on vegetative cells in the stationary phase of growth (Lereclus et al., 1996). PlcR expression is negatively regulated by the sporulation key factor Spo0A indicating that this gene is only temporally expressed on vegetative cells before the onset of sporulation (Lereclus et al., 1996). PlcR protein senses cell density and is therefore a quorum sensing mechanism (Slamti and Lereclus, 2002). The *papR* gene, encoding a 48 amino acid peptide and located downstream of *plcR*, is activated by PlcR and the gene product is secreted. Outside the cell, PapR is degraded by extra cellular proteases and the carboxi-terminus end pentapeptide is internalized to the bacterium cytoplasm by the oligopeptide permease Opp (Slamti and Lereclus, 2002). Inside the cell, the pentapeptide binds PlcR activating the capacity of PlcR to bind to the “PlcR box” sequence activating gene expression (Slamti and Lereclus, 2002). It was also shown that the PlcR activating- peptide confers strain-specificity to the activation of the PlcR-regulon, single amino acid changes on the activating PapR peptide were enough for strain specific induction of the PlcR regulon (Slamti and Lereclus, 2002). These results suggest that quorum sensing of related Bt strains is restricted by the sequence homology of the c-terminal pentapeptide of PapR. Fig. 1 shows the PlcR regulon network including the gene targets and the regulation of PlcR activation by PapR protein.

Insecticidal Toxins

Classification and Nomenclature

The mayor determinants of Bt insecticidal properties are the δ -endotoxins (Schnepf et al., 1998). The δ -endotoxins form two multigenic families, *cry* and *cyt*. Cry proteins are specifically toxic to orders of insects, *Lepidoptera*, *Coleoptera*, *Hymenoptera* and *Diptera*. In contrast, Cyt toxins are mostly found in Bt strains active against *Diptera*, although few exceptions of *Coleoptera* active strains containing Cyt proteins have been documented (Guerchicoff et al., 2001). Currently more than 74 Cry groups and 3 Cyt with more than 700 members have been characterized and classified (Crickmore et al., 2014). Besides these crystals proteins, some Bt and *B. cereus* strains produce a third group of insecticidal proteins called Vip (Estruch et al., 1996). In contrast to crystal proteins, Vip proteins are synthesized during the vegetative growth-phase of the bacterium and secreted into the medium. Including Cyt and VIP toxins, Bt produces at least six different families that are not related in structure, the three-domain (3D) family, the Bin-family and the MTX family. Classification and diversity of Cry, Cyt and Vip toxins has been reviewed recently (Adang et al., 2014).

The definition of Cry proteins is rather broad: a parasporal inclusion protein from Bt that exhibits toxic effect to a target organism, or any protein that has obvious sequence similarity to a known Cry protein (Crickmore et al., 1998). This definition includes the Cyt toxins although it is agreed to give the mnemonic Cyt to Cry proteins that are structurally related to Cyt toxins (Crickmore et al., 1998). The nomenclature of Cry and Cyt proteins is based on primary sequence identity among different gene sequences. Crystal proteins receive the mnemonic Cry or Cyt and four hierarchical ranks consisting of numbers, capital letters, lower case letters and numbers (e.g., Cry1Ab1). The ranks are given depending on the sequence identity shared with other Cry or Cyt proteins. A different number (first rank) is given to a protein if it shares less than 45% identity with all the others Cry proteins (Cry1, Cry2 etc.). The capital letter (second rank) is given if the protein shares less than 78% but more than 45% identity with a particular group of Cry proteins (e.g., Cry1A, Cry1B etc.). The third rank gives a lower case letter to distinguish proteins that share more than 78% but less than 95% identity with other Cry proteins (e.g., Cry1Aa, Cry1Ab etc.). Finally a number is given to distinguish proteins that share more than 95% identity but which are not identical and that should be considered variants of the same gene (Crickmore et al., 1998). Although this system does not take into account the insect specificity of Cry toxins, the subgroups of Cry toxins show toxicity against a particular genus of insects (Cry1 to lepidopterans, Cry3 to coleopterans etc.). In the case of dipteran active toxins, it is surprising the high amount of different subgroups active against mosquitoes that represent Cry proteins that share low sequence similarity (e.g. Cry1C, Cry2Aa, Cry4, Cry11 etc.).

Different proteins not related phylogenetically comprise the Cry family. Among these, the 3-Domain Cry family, the bigger group of Cry proteins, binary toxins and Mtx toxins related to toxins produced by *Bacillus sphaericus* have been described (Crickmore et al., 1998). The members of the 3-Domain family are globular molecules containing three distinct domains connected by single linkers. The alignment of their protein sequences revealed the presence of five conserved sequence blocks, although, some blocks are absent in some sub-groups of the 3-Domain family. One particular feature of the members of this family is the presence of protoxins with two different lengths. One large group of protoxins is approximately twice as long as the majority of the toxins. The C-terminal extension found in the longer protoxins is dispensable for toxicity but is believed to play a role in the formation of the crystal inclusion bodies within the bacterium (de Maagd et al., 2001).

Cyt toxins comprise three highly related gene families (Cyt1, Cyt2 and Cyt3) (Crickmore et al., 1998, 2002). Analysis of amino acid sequences shows that the different Cyt versions show a high degree of conservation in predicted α -helices and β -sheets (Guerchicoff et al., 2001). Cyt toxins are also synthesized as protoxins and small portions of the N-terminus and C-terminus are removed to activate the toxin (Li et al., 1996). Cyt proteins are almost exclusively found on dipteran active strains although a few exceptions have been found (Guerchicoff et al., 2001). Cyt toxins synergize the toxic effect of some Cry proteins and also that of the *B. sphaericus* binary toxin (Wu et al., 1994; Wirth et al., 2001). In the case of Cry and Cyt proteins it is widely accepted that the primary action of these toxins is the formation of lytic pores on the midgut cells of susceptible insects. Fig. 2 shows the phylogenetic dendrogram of Cry and other Bt toxins.

Finally, Vip proteins comprise three families with seven members. The mechanism of action of these proteins has not been clearly described. Nevertheless, the three dimensional structure of Vip2 protein suggests that it may have ADP-ribosylating activity (Craig et al., 1999). Vip3A is a pore forming toxin of 88-kDa that forms ion channels in target membranes and in planar lipid bilayer (Lee et al., 2003). It has a broad lepidopteran spectrum and binds to different protein receptors that are different from Cry1A or Cry1C toxins receptors (Lee et al., 2003; Mahon et al. 2012; Abdelkefi-Mesrati et al., 2011).

The Bin-like toxins named Cry35 and Cry36 are active against some coleopteran larvae. They are named Bin like since they share some similarities with the dipteran specific binary toxins (Bin) produced by *Lysinibacillus sphaericus*. These are also pore-forming toxins that form ionic channels in black lipid bilayer at acidic conditions, which mimics the pH of the Coleopteran larvae (Masson et al., 2004).

The Mtx-like Cry family contains members with similarities to the Mtx toxin from *L. sphaericus* that shows mosquitocidal activity. Some of the Mtx-like Cry are active against Coleopteran insects (Cry15, Cry23, Cry33, and Cry38); others are toxic to Dipteran larvae (Cry60); or show dual activity against Coleopteran and Hemipteran (Cry51) (Crickmore et al., 2014). The mechanism of action of these toxins is not completely understood.

Structure of Toxins

The crystal structure of Cry1A (PDB 1CIY for Cry1Aa, 4ARX for Cry1Ac) (lepidopteran specific); Cry3 and Cry8 (PDB 1DLC for Cry3Aa, 1JL6 for Cry3Bb, 3EB7 for Cry8Ea) (coleopteran specific); Cry4 (PDB 2C9K for Cry4Aa, 1W99 for Cry4Ba) (dipteran specific) and Cry5 (PDB 4D8M) (nematode specific) trypsin activated toxins and Cry2Aa (PDB 1I5P) (dipteran-lepidopteran specific) protoxin have been solved (Grochulski et al., 1995; Li et al., 1991; Galitsky et al., 2001; Morse et al., 2001; Boonserm et al., 2005, 2006; Guo et al., 2009; Hui et al., 2012; see "Relevant Websites section").

Although the sequence similarity between these toxins is very low (20% and 17% identity of Cry2Aa with Cry3Aa and Cry1Aa respectively) the overall structural topology of these proteins is very similar. Fig. 3 shows the three-dimensional structure of Cry1A, Cry3Aa toxins and Cry2Aa protoxin (Morse et al., 2001). The structure is composed of three structural domains. Domain I is a seven α -helix bundle in which a central helix α -5 is surrounded by six outer helices. This domain has been implicated in the membrane channel formation. The six α -helices are amphipathic and are long enough to span the 30-Å thick hydrophobic region of a membrane bilayer. Cry2Aa protoxin has an extra 49-amino acid region forming two extra α -helices in the amino-terminal end

Fig. 2 Dendrogram of Cry protein sequences. Three domain (left panel) and other Cry protein sequences (right panel). Update and dendrogram analysis can be found in <http://www.btnomenclature.info/>.

Fig. 4 Proteins with structural similarity to the three domains of Cry toxins.

that are cleaved out after proteolytic activation of the toxin (Fig. 3, 21). Domain II consist of three anti-parallel β -sheets packed around a hydrophobic core in a “beta-prism”. This domain represents the most divergent part in structure among Cry toxin molecules (de Maagd et al., 2001) and has been described as the specificity-determining domain. Finally, domain III is a β -sandwich of two antiparallel β -sheets. Several lines of evidence indicate that domain III is implicated insect specificity and therefore involved in receptor binding. Although additional roles of this domain, as pore-formation have been suggested (Schwartz et al., 1997; de Maagd et al., 2001).

Fig. 4 shows the analysis of structural similarities of the three domains of Cry toxins with other proteins. This analysis revealed interesting features that could give hints on the possible role of these domains in the mode of action of Cry proteins. Domain I shares structural similarities with other pore forming toxins like colicin Ia and N (PBB codes: 1cii, 1a87), haemolysin E (1qoy), and diphtheria toxin (1ddt), supporting the role of this domain in pore-formation. In the case of domain II, structural similarities with several carbohydrate-binding proteins like vitelline (1vmo), lectin jacalin (1jac), and lectin Mpa (1jot). For domain III, also carbohydrate-binding proteins with similar structures were identified as the cellulose binding domain of 1,4-*b*-glucanase CenC (1ulo), galactose oxidase (1gof), sialidase (1eut), *b*-glucuronidase (1bhg), the carbohydrate-binding domain of xylanase U (1gmm) and *b*-galactosidase (1bgl). These results suggests that carbohydrate moieties could have an important role in the mode of action of 3-Domain Cry toxins. As will be discussed later the involvement of carbohydrate moieties in the mode of action of some Cry toxins has been demonstrated.

Fig. 3 shows also the ribbon representation of the three dimensional structure of Cyt2Aa toxin (PDB 1CBY) (Li et al., 1996). The structure of other Cyt toxins have also been solved and reported (PDB 3RON for Cyt1Aa, 2RCI for Cyt2Ba). (Cohen et al., 2008, 2011; see “Relevant Websites section”). Cyt2Aa has single domain of α/β architecture comprising two outer layers of α -helices hairpins wrapped around a β -sheet. Cyt2Aa protoxin is organized as a dimer. Proteolytic activation releases the active Cyt2Aa toxin monomer (Gazit et al., 1997). Based on the length of the secondary structures it was proposed that the inner core of β -sheets (β -5, β -6, β -7 and β -3) could span the cell membrane (Gazit et al., 1997). However, analysis of membrane insertion capabilities of synthetic peptides corresponding to the different secondary structural elements suggested that α -helices A and C, rather than the β -sheets, could be the elements responsible for membrane interaction (Gazit et al., 1997). In the case of Cyt1Aa it was shown that the N-terminal part of the toxin containing the α -helix hairpins is involved in toxin oligomerization while the β -sheets are involved in membrane insertion (Rodríguez-Almazán et al., 2011). Also, it was shown that certain mutations in the Cyt1Aa α -helix C affected oligomerization, membrane insertion and toxicity suggesting also that oligomerization of Cyt1Aa is important for membrane insertion (López-Díaz et al., 2013).

Vip2A and Vip1A were isolated and characterized from a *B. cereus* strain (Warren, 1997). The structural genes *vip2* and *vip1* form an operon and both proteins are required for toxicity. Therefore Vip1 and Vip2 form a binary toxin. Fig. 3 shows the three-dimensional structure of Vip2 protein (PDB 1QS1) (Han et al., 1999). Vip2 is a mixed α/β protein and is divided into two domains. The domains are structurally homologous although they share low amino acid identity. The overall fold of each domain resembles

the catalytic domains of classical A-B toxins that have two components, a binding component (Vip1 presumably) and a catalytic ADP-ribosylating component (Vip2) (Warren, 1997). It is proposed that Vip2A attaches a ADP-ribose moiety to a monomeric G-actin, affecting its polymerization and the cytoskeleton integrity (Jucovic et al., 2008).

The structure of Bin-like Cry34 and Cry35 proteins have been solved. Fig. 3 shows the three-dimensional structure of these proteins (PDB: 4JP0 and 4JOX) (Kelker et al., 2014). Cry35 has similarities with BinB toxin from *L. sphaericus* and Cry34 shows similarities with other pore forming toxins such as Aegerolysin family of proteins (Kelker et al., 2014).

Finally, regarding to the Mtx-Cry toxins only the structure of Cry23 was solved. Fig. 3 also shows the three-dimensional structure of Cry23 protein (PDB 4RHZ). This protein associates with Cry37, which has no similarities with other Mtx-like Cry toxins but together form a pore forming toxin (de Maagd et al., 2003).

Evolution of 3-Domain Toxins

The increasing number of Cry toxins and the wide variety of target organisms that these proteins have, puts forward the question as how evolution of this protein family create such a diverse arsenal of toxins. It has been proposed that toxins co-evolved with their target insects (de Maagd et al., 2001). However, there are no studies that correlate the geographical distribution and Cry protein content of Bt strains and the distribution of their target insect species in nature. In one particular study, a Bt strain collection obtained from different climate regions of Mexico revealed that putative novel *cry* genes were more frequently found on Bt strains isolated from tropical regions where the insect diversity is high (Bravo et al., 1998). These results suggest that Cry toxins and insects may co-evolve although more comprehensive studies are needed to support this assumption.

The results of phylogenetic analysis of the complete Cry toxin or protoxin protein showed a broad correlation with toxicity (Bravo, 1997). However, the analysis of the phylogenetic relationships of the isolated domains revealed interesting features regarding the creation of diversity in this family of proteins (Bravo, 1997; de Maagd et al., 2001). The analysis of phylogenetic relationships of isolated domain I and domain II sequences revealed that these domains coevolved. In the case of domain II, phylogenetic relationships showed a topology clearly related to the specificity of the toxin proteins (Bravo, 1997). This result is not surprising in spite of the fact that domain II is involved in receptor recognition and is therefore a determinant of insect specificity (Bravo, 1997; de Maagd et al., 2001). Surprisingly, phylogenetic relationships of domain I sequences, that is involved in the pore formation of the toxin, showed a topology also clearly related to the specificity of the toxin proteins (Bravo, 1997; de Maagd et al., 2001) suggesting that different types of domain I have been selected for acting in particular membrane conditions of their target insect (Bravo, 1997; de Maagd et al., 2001). The analysis of domain III sequences, revealed a different topology due to the fact that several examples of domain III swapping among toxins occurred (Bravo, 1997; de Maagd et al., 2001). Some toxins with dual specificity (coleopteran, lepidopteran) are clear examples of domain III swapping among coleopteran and lepidopteran specific toxins (Bravo, 1997; de Maagd et al., 2001). To illustrate domain III swapping in natural toxins, Cry1B toxins are a good example. Five different Cry1B toxins have been described. These toxins share almost identical domain I and domain II sequences. However, Cry1B domain III sequences cluster with other Cry genes suggesting a very active process of domain III exchanges: Cry1Ba domain III sequence is closely related to domain III sequences of Cry1Jb, Cry8Aa and Cry9Da (see Fig. 5). In contrast Cry1Bb and Cry1Bc share similar domain III sequences between them. In the case of Cry1Be, domain III clusters with domain III from Cry1Cb and Cry1Eb. Finally Cry1Bd domain III is similar to domain III of Cry1Ac toxin. For some Cry1B toxins bioassays show that some of these toxins have different insect specificities, Cry1Ba is active against the coleoptera insect Colorado potato beetle, while Cry1Bd has higher activity against the lepidoptera *Plutella xylostella* than Cry1Ba and Cry1Bb toxins. A more comprehensive analysis of toxicity of Cry1B toxins could establish the relevance of domain III swapping in toxicity. However, this result suggests that domain III swapping could create novel specificities. Indeed, *in vitro* domain III swapping of certain Cry1 toxins results in changes in insect specificity (Bosch et al., 1994; de Maagd et al., 2000, 2001). Fig. 5 shows the topology of the phylogenetic relationships of domain III sequences and the representation of the natural Cry toxins in which domain III swapping occurred.

The phylogenetic analysis of the Cry toxin family shows that the great variability in the biocidal activity of this family has resulted from two fundamental evolutionary process: (1) Independent evolution of the three structural domains and (2) domain III swapping among different toxins. These two processes have generated proteins with similar modes of action but with very different specificities (Bravo, 1997; de Maagd et al., 2001).

Two different types of 3D protoxins have been described, short protoxins of around 70 kDa and long protoxins of 130 kDa. The three dimensional structure of two protoxins one short, Cry2Aa, and one long, Cry1Ac, have been solved (Morse et al., 2001; Evdokimov et al., 2014). In the case of Cry2Ab the N-terminal fragment corresponds to two small α -helices that are hiding domain II regions presumably involved in receptor interaction (Morse et al., 2001). In the case of Cry1Ac protoxin, the C-terminal end is composed of four additional domains IV to VII (Evdokimov et al., 2014). It is remarkable that C-terminal region is extremely conserved among all long Cry protoxins. The role of the C-terminal domains in toxin action still remains to be analyzed. Domains IV and VI are composed of α -helices, they resemble structural/interaction domains. Domains V and VII are form of β -strands and resembled carbohydrate-binding modules (Evdokimov et al., 2014). The conserved structure of different 3D-Cry toxins that share low sequence identity and that show different insect specificity suggests that the mode of action is conserved in different insect orders (Pardo-lópez et al., 2013).

Intoxication Syndrome of Cry Toxins

Solubilization and Proteolytic Activation

Proteolytic processing of Cry toxins is a critical step involved not only on toxin activation but also on specificity (Haider and Ellar, 1989; Haider et al., 1989) and insect resistance (Oppert et al., 1997; Shao et al., 1998). Besides pH, Lepidopteran and

Coleopteran insects differ on the type of proteases present on the insect gut; serine proteases are the main digestive proteases of *Lepidoptera* and *Diptera*, whereas cysteine and aspartic proteases are abundant in *Coleoptera* midguts (Terra and Ferreira, 1994). It has been reported that enhanced degradation of Cry toxins is associated with the loss of sensitivity of fifth instar *S. littoralis* larvae to Cry1C (Keller et al., 1996) and that serine protease inhibitors enhanced the insecticidal activity of some Bt toxins up to 20 fold (MacIntosh et al., 1990). More recently, it was found that the low toxicity of Cry1Ab toxin to *Spodoptera frugiperda* could be explained in part by rapid degradation of the toxin on the insect midgut (Miranda et al., 2001). For several Cry proteins inactivation within the insect gut involves intramolecular processing of the toxin (Choma et al., 1990; Lambert et al., 1996; Audtho et al., 1999; Pang et al., 1999; Miranda et al., 2001). However, for several other toxins, intramolecular processing of Cry toxins is not always related to loss of toxicity and sometimes is required for proper activation of the toxin (Dai and Gill, 1993; Zalunin et al., 1998; Yamagiwa et al., 1999). Therefore, in some cases, differential proteolytic processing of Cry toxins in different insects is a limiting step in the toxicity of Cry toxins (Miranda et al., 2001).

During activation by midgut proteases all protoxins are processed in the N-terminal end losing short peptides of around 40 amino acids while only long protoxins are processed also at the C-terminal end losing more than 500 amino acid fragment. It was proposed that the C-terminal region of the long protoxins could be involved in crystal formation and that it could be dispensable for toxicity since it is cleaved out during toxin activation. However, the recent structure of this C-terminal region suggest that this region may be playing an additional role in toxin action that remains to be analyzed in the future. After protease activation a 65 kDa toxic fragment is produced that is composed of three domains (de Maagd et al., 2001).

One interesting feature of Cry toxin activation is the processing of the N-terminal end of the toxins. The 3-dimensional structure of Cry2Aa protoxin showed that two α -helices of the N-terminal region occlude a region of the toxin involved in the interaction with the receptor (Morse et al., 2001; Fig. 3). Several lines of evidences suggest that the processed N-terminal peptide of Cry protoxins might prevent binding to non-target membranes (Martens et al., 1995; Kouskoura et al., 2001; Bravo et al., 2002b). *E. coli* cells producing Cry1Ab or Cry1Ca toxins lacking the N-terminal peptide were severely affected in growth (Martens et al., 1995; Kouskoura et al., 2001). It was speculated that the first 28 amino acids prevented the Cry1A toxin from inserting into the membrane (Martens et al., 1995; Kouskoura et al., 2001). Recently, it was found that a Cry1Ac mutant that retains N-terminus end after trypsin treatment binds nonspecifically to *M. sexta* membranes and was unable to form pores on *M. sexta* brush border membrane vesicles (Bravo et al., 2002b). Therefore, processing of the N-terminal end of Cry protoxins may unmask a hydrophobic patch of the toxin involved in toxin-receptor or toxin-membrane interaction (Morse et al., 2001; Bravo et al., 2002b).

Receptor Identification

It is generally accepted that 3D-Cry toxins bind to receptors located in brush border membranes of midgut cells of susceptible insects and exert their toxicity by inserting into the membrane forming pores that lyse cells by osmotic shock (Vachon et al., 2012; Pardo-lópez et al., 2013). The major determinant of Cry toxin specificity is the interaction with specific receptors on the insect gut of susceptible insects (Jenkins and Dean, 2000). Therefore, receptor identification is fundamental for determining the molecular basis of Cry toxin specificity and also in insect resistance management that in many cases has been shown to correlate with defects on receptor binding (Ferré and Van Rie, 2002). Different insect gut molecules that bind Cry toxins have been characterized in different insect species (Pigott and Ellar, 2007; Likitvivatanavong et al., 2011). These include aminopeptidase-N, alkaline phosphatase and cadherins (Pigott and Ellar, 2007). However, other Cry binding molecules as ABCC2 transporters in lepidopteran insects (Heckel, 2012), amylases or glucosidases in mosquitoes (Fernández-Luna et al., 2010; Zhang et al., 2013) or sodium solute symporter in coleoptera (Contreras et al., 2013) have been recently described.

In *M. sexta*, the Cry1Aa, Cry1Ab and Cry1Ac proteins bind to a 120 kDa aminopeptidase-N (APN) (Knight et al., 1994; Garczynski and Adang, 1995; Denolf et al., 1997) and to a 210 kDa cadherin-like protein (Bt-R₁) (Belfiore et al., 1994; Vadlamudi et al., 1995). Cadherins represent a large family of glycoproteins that are responsible for inter-cellular contacts. These proteins are transmembrane proteins with a cytoplasmic domain and an extra cellular ectodomain with several cadherin repeats (12 in the case of Bt-R₁). The ectodomain contain calcium-binding sites, integrin interaction sequences and cadherin binding sequences. In *Bombyx mori*, Cry1Aa binds to a 175 kDa cadherin-like protein (Bt-R₁₇₅) (Nagamatsu et al., 1998, 1999) and to a 120 kDa APN (Yaoi et al., 1997). In *Heliothis virescens* Cry1Ac binds to two proteins of 120 kDa and 170 kDa both identified as APN (Gill et al., 1995; Oltean et al., 1999). Also, a cadherin-like protein is involved in the mode of action of Cry1Ac toxin in *Heliothis virescens* (Gahan et al., 2001). In *Plutella xylostella* and *Lymantria dispar* APNs were identified as Cry1Ac receptors (Valaitis et al., 1995; Lee et al., 1996; Denolf et al., 1997; Luo et al., 1997). In *Lymantria dispar*, besides APN and cadherin-like receptors, a high molecular weight anionic protein (Bt-R₂₇₀) that binds Cry1A toxins with high affinity was identified (Valaitis et al., 2001). For Cry1C toxin an APN-receptor molecule was identified in *Spodoptera litura* (Agrawal et al., 2002). Sequence analysis of various APN from lepidopteran insects suggests that APN's group into at least four classes (Oltean et al., 1999). *P. xylostella* and *B. mori* produce the four classes of APN and it is anticipated that several other lepidopteran insects may also produce the four isoforms (Nakanishi et al., 2002). Cry1A binding to the different *B. mori* APN isoforms revealed that this toxin only binds the 115 kDa isoform in ligand-blot binding analysis (Nakanishi et al., 2002).

Surface plasmon resonance experiments showed that the binding affinity of Cry1A toxins to the *M. sexta* APN is on the range of 100 nM (Jenkins and Dean, 2000), while that of cadherin-like receptors (Bt-R₁) is on the range of 1 nM (Vadlamudi et al., 1995).

The differences of binding affinities between APN and Bt-R₁ suggest that binding to Bt-R₁ might be the first event on the interaction of Cry1A toxins with microvilli membranes and, therefore, the primary determinant of insect specificity.

Different experimental evidence suggests the involvement of both Cry1A toxins receptors (APN and cadherin-like) in toxicity. Expression of the *M. sexta* and *B. mori* cadherin-like proteins, Bt-R₁ and Bt-R₁₇₅ respectively, on the surface of different cell lines cells render these cells sensitive to Cry1A toxins (Nagamatsu et al., 1999; Dorsch et al., 2002; Tsuda et al., 2003). Cry1Aa toxin was shown to lyse isolated midgut epithelial cells, this toxic effect was inhibited if the cells were preincubated with anti-Bt-R₁₇₅ antisera in contrast with the treatment with anti-APN antisera, suggesting that cadherin-like protein Bt-R₁₇₅ is a functional receptor of Cry1Aa toxin (Hara et al., 2003). Also, a single-chain antibody (scFv73) that inhibits binding of Cry1A toxins to cadherin-like receptor, but not to APN, reduced the toxicity of Cry1Ab to *M. sexta* larvae (Gómez et al., 2001). Moreover, disruption of a cadherin gene by a retrotransposon-mediated insertion and its linkage to high levels of resistance to Cry1Ac toxin in *H. virescens* YHD2 larvae (Gahan et al., 2001). Overall, these results suggests that binding to cadherin-like receptor is an important step in the mode of action Cry1A toxins.

Regarding APN-receptor, several reports argue against the involvement of this protein in toxin activity. Mutants of Cry1Ac toxin affected on APN-binding retained toxicity levels to *M. sexta* as the wild-type toxin (Burton et al., 1999). Expression of APN in heterologous systems did not resulted in Cry1A sensitivity (Denolf et al., 1997) and, as mentioned above, an APN-antibody did not protect *B. mori* midgut cells from Cry1Aa toxic effect in contrast to a cadherin-antibody (Hara et al., 2003). However, two recent reports clearly demonstrate the importance of this molecule on the mode of action of Cry1 toxins. Inhibition of APN production on *S. litura* larvae by dsRNA interference showed that insects with low APN levels became resistant to Cry1C toxin (Rajagopal et al., 2002). Also, heterologous expression of *M. sexta* APN in midguts and mesodermal tissues of transgenic *Drosophila melanogaster* caused sensitivity to Cry1Ac toxin (Gill and Ellar, 2002). Additionally, previous reports demonstrated that incorporation of *M. sexta* APN into black lipid bilayers lower the concentration of toxin needed for pore formation activity of Cry1Aa toxin (Schwartz et al., 1997b). Finally, all Cry1A APN-receptors are anchored to the membrane by a glycosyl phosphatidylinositol (GPI) (Knight et al., 1994; Garczynski and Adang, 1995; Denolf et al., 1997; Oltean et al., 1999; Nakanishi et al., 2002; Agrawal et al., 2002). The phosphatidylinositol specific phospholipase C (PIPLC) treatment of *Trichoplusia ni* brush border membrane vesicles (BBMV), resulting in cleavage of GPI-anchored proteins from membrane, reduced Cry1Ac pore-formation activity (Lorenz et al., 1997). These reports suggest that APN binding is also an important step in the mode of action of Cry1 toxins. Fig. 6 shows the representation of the APN and cadherin Cry1A receptors.

In the case of the dipteran specific Cry11A and Cry4B toxins, two binding-proteins of 62 and 65 kDa were identified on brush border membrane vesicles from *Aedes aegypti* larvae (Buzdin et al., 2002). The identity Cry11A and Cry4 receptors in mosquitoes include cadherin, ALP, APN, alpha-amylases and glucosidases (Fernández-Luna et al., 2010; Zhang et al., 2013; Likitvatanavong et al., 2011).

One interesting feature of the Cry1 receptor molecules identified so far is that all these proteins are glycosylated. As mentioned before, it is interesting to note that domain II and domain III of Cry toxins have structural homology to proteins domains that interact with carbohydrates. In the case of Cry1Ac, Cry5 and Cry14 toxins different experimental evidence suggest a role of carbohydrate recognition in the mode of action of these toxins (Masson et al., 1995; Griffiths et al., 2001). However, the structural similarities of domain II and III with carbohydrate-binding proteins does not exclude the possibility that these domains may have protein-protein interactions with the receptor molecules. In fact some loop regions of domain II of Cry1Ab and the Bt-R₁ receptor have protein-protein interaction (Gómez et al., 2002a). The interaction between toxin and its receptor can be complex. Interestingly, binding of Cry1Ac to two sites on the purified APN from *M. sexta*, and the interaction is inhibited by N-acetyl-galactosamine, which do not inhibit the binding of Cry1Aa and Cry1Ab to its receptors (Masson et al., 1995). Only one Cry1Ac binding site on APN is also recognized by Cry1Aa and Cry1Ab toxin (Masson et al., 1995).

Fig. 6 Receptor molecules of Cry1A proteins. *K_d* values are average affinity values of Cry1A toxins to Aminopeptidase-N and Cadherin receptors.

Toxin Binding Epitopes

The identification of epitopes involved in Cry toxin-receptor interaction will provide insights on the molecular basis of insect specificity and could help in the characterization of resistant insect-populations in nature as to develop strategies to design toxins that could overcome receptor point mutations leading to Cry toxin-resistance.

The toxin binding epitopes have been mapped for several Cry toxins. Domains II and III are most variable regions of Cry toxins and had therefore been subject to mutagenesis studies to determine their role on receptor recognition. Domain II was first recognized as an insect specificity determinant domain based on hybrid-toxin construction using *cry* genes with different specificity (Ge et al., 1989). Site-directed mutagenesis studies of Cry1A toxins showed that some exposed loop regions, loop α -8, loop 2 and loop 3, of domain II are involved on receptor recognition (Rajamohan et al., 1996a,b; Jenkins et al., 2000; Lee et al. 2000, 2001). Mutagenesis of amino acid residues present in loop 2 region of Cry1Ab toxin and characterization of these mutants with respect to binding to insect BBMV, showed that RR368–9 residues have an important role in the reversible binding of the toxin to BBMV, while residue F371 is involved in the irreversible binding of the toxin (Rajamohan et al., 1996b, 1995; Jenkins and Dean, 2000). Reversible binding is related to the initial interaction of the toxin to the receptor while irreversible binding is related to the insertion of the toxin into the membrane (Rajamohan et al., 1995). This result was interpreted as if residue F371 was involved on membrane insertion (Rajamohan et al., 1995, 1996b). Also, evidence has been provided showing that loop 2 residues RR368–9 of Cry1Ab are involved on APN binding since this mutant showed no binding to purified APN in surface plasmon resonance experiments (Jenkins and Dean, 2000; Lee et al., 2000). In this regard it is interesting to note that a truncated derivative of Cry1Ab toxin containing only domain II-III was still capable of receptor interaction but was affected on irreversible binding (Flores et al., 1997). Therefore it is likely that mutations in F371 residue affect membrane insertion probably by interfering a conformational change, necessary for membrane insertion, after initial recognition of the receptor or as originally proposed this residue could be directly involved in membrane interaction (Rajamohan et al., 1995). Phylogenetic relationship studies of different Cry1 loop 2 sequence show that there is a correlation between the of loop 2 amino acid sequence and cross-resistance with several Cry1 toxins in resistant insect populations, implying that this loop region is an important determinant of receptor recognition (Tabashnik et al., 1994; Jurat-Fuentes and Adang, 2001). Overall these results suggest that loop 2 of Cry1A toxins play an important role in the recognition of receptors. Regarding loop α -8 and loop 3, mutations of some residues in these regions of Cry1A toxins affected reversible binding to BBMV or purified APN-receptor (Rajamohan et al., 1996a; Lee et al., 2001). The close related toxins Cry1Ab and Cry1Aa have different loop 3 amino acid sequences even though they interact with the same receptor molecules (Rajamohan et al., 1996a). Analysis of binding of Cry1Ab and Cry1Aa to the cadherin-like Bt-R₁ receptor in ligand blot experiments and competition with synthetic peptides corresponding to the toxin exposed loop regions, showed that, besides loop 2, loop 3 of Cry1Aa toxin was important for Bt-R₁ recognition (Gómez et al., 2002a). Although Cry1A loop 1 region seems not to play an important role in receptor recognition this is certainly not the case for other Cry toxins. Mutagenesis of Cry3A loop 1 residues showed that this region, besides loop 3, is important for receptor interaction in *Coleopteran* insects (Wu and Dean, 1996). Loop 1 residues of two Cry toxins with dual insecticidal activity (Cry1Ca and Cry2Aa) are important for dipteran toxicity but not for lepidopteran activity (Widner and Whiteley, 1990; Smith and Ellar, 1994; Morse et al., 2001). Besides loop1 of Cry1C toxin, loops 2 and 3 are important for toxicity to dipteran and lepidopteran insects (Abdul-Rauf and Ellar, 1999). In the case of Cry2Aa toxin an amino acid region involved on lepidopteran activity was not located in the loop regions but was located to a different part of domain II (Morse et al., 2001). These results show that the loop regions of domain II are important determinants for receptor interaction although other regions of this domain, in certain toxins, could also participate in receptor recognition.

As mentioned previously, domain III swapping showed that this domain is involved in receptor recognition (Bosch et al., 1994; de Maagd et al., 2000), and has been used as an evolutionary mechanism of these toxins (de Maagd et al., 2001; Bravo, 1997). The domain III swapping of Cry1Ac to Cry1Ab toxins showed that Cry1Ac domain III was involved in APN recognition (Lee et al., 1995; de Maagd et al., 1999a). The interaction of Cry1Ac domain III and APN was dependent on N-acetylglucosamine residues (Burton et al., 1999; Lee et al., 1999). Mutagenesis studies of Cry1Ac domain III identified residues ⁵⁰⁹QNR⁵¹¹, N506 and Y513 as the epitope for sugar recognition (Burton et al., 1999; Lee et al., 1999). The three dimensional structure of Cry1Ac in the presence of the sugar confirmed that these residues are important for Gal-Nac recognition (Li et al., 2001). In the case of Cry1Ac toxin, a sequential binding mechanism to APN receptor has been proposed (Jenkins et al., 2000). The interaction of domain III to a N-acetyl galactosamine moiety in the receptor precedes the binding of loop regions of domain II (Jenkins et al., 2000).

Receptor Binding Epitopes

In regard to the receptor binding epitopes, a region of 63 residues (I135-P198) involved in Cry1Aa binding was identified by analysis of truncated derivatives of *B. mori* APN. This site was specific for Cry1Aa toxin since it was not involved in Cry1Ac binding (Yaoi et al., 1999; Nakanishi et al., 2002). Nevertheless, this binding region is shared with APN molecules that do not bind Cry1Aa toxin when assayed by toxin overlay assays (Nakanishi et al., 2002). This result can be explained if the epitope mapped was not accessible in native conditions. In fact it has been shown that denaturation of *M. sexta* APN exposes binding epitopes hidden under nondenaturing conditions (Daniel et al., 2002). Therefore, the role of the mapped binding epitope in *B. mori* APN in toxicity remains to be analyzed.

Regarding cadherin-like receptors, a Cry1A binding epitope was mapped in Bt-R₁ and Bt-R₁₇₅ receptor molecules by the analysis of truncated derivatives of these receptors in toxin overlay assays (Nagamatsu et al., 1999; Dorsch et al., 2002). In the case of Bt-R₁

and Bt-R₁₇₅ 70 amino acid residues toxin binding region were mapped to cadherin repeat number 11 that is close to the membrane spanning region (Nagamatsu et al., 1999; Dorsch et al., 2002). Using a library of single chain antibodies displayed in M13 phage, a second Cry1A toxin-binding region was mapped in Bt-R₁ receptor (Gómez et al., 2001). An scFv antibody (scFv73) that inhibited binding of Cry1A toxins to the cadherin-like receptor Bt-R₁, but not to APN, and reduced the toxicity of Cry1Ab to *M. sexta* larvae was identified (Gómez et al., 2001). Sequence analysis of CDR3 region of scFv73 molecule led to the identification of an eight amino acid epitope of *M. sexta* cadherin-like receptor, Bt-R₁, (⁸⁶⁹HITDTNNK⁸⁷⁶) involved in binding of Cry1A toxins. This amino acid region maps in the cadherin repeat number seven (Gómez et al., 2001). Using synthetic peptides of the exposed loop regions of domain II of Cry1A toxins, loop 2 was identified as the cognate binding epitope of the *M. sexta* receptor Bt-R₁ ⁸⁶⁹HITDTNNK⁸⁷⁶ site (Gómez et al., 2002a). This finding highlights the importance of ⁸⁶⁹HITDTNNK⁸⁷⁶ binding epitope since extensive mutagenesis of loop 2 of Cry1A toxins has shown that this loop region is important for receptor interaction and toxicity (Rajamohan et al., 1995, 1996b; Jenkins and Dean, 2000; Jenkins et al., 2000). Accumulating evidence indicate that proteins can interact through amino acid sequences displaying inverted hydropathic profiles (Blalock, 1995). The interaction of loop 2 with Bt-R₁ ⁸⁶⁹HITDTNNK⁸⁷⁵ region was shown to be determined by hydropathic complementarity and that the binding epitope (⁸⁶⁵NITHITDTNN⁸⁷⁵) could be larger than the epitope identified by sequence similarity to the scFv antibody (Gómez et al., 2002a). As mentioned previously, it is generally accepted that the toxic effect of Cry proteins is exerted by the formation of a lytic pore. However, it has also been shown that Cry1A toxins target molecules involved in cell-cell interactions (cadherin) within susceptible hosts as is the case of several other pathogens (Dorsch et al., 2002). Targeting cell junction molecules seems to be representative of those bacteria that disrupt or evade epithelial barriers in their hosts. In this regard it is remarkable that Cry1A toxins interact with at least two structural regions that are not close together in the primary sequence of Bt-R₁ (cadherin repeats 7 and 11). Although we cannot exclude that both sites could be located near by in the three dimensional structure of Bt-R₁, we speculate that binding of Cry1A toxins could cause a conformational change in cadherin molecule that could have a consequence with the interaction with other cell-adhesion proteins and consequently on the disruption of the epithelial cell layer. Fig. 7 shows a schematic representation of the interaction of Cry1A toxins with the Bt-R₁ receptor.

Fig. 7 Structural regions on *M. sexta* cadherin receptor (Bt-R₁) involved in Cry1A binding. Ectodomains (EC) 7 and 11 contain Cry1A binding epitopes.

As mentioned previously, mutagenesis studies have shown that besides domain II loop 2, loop α -8 and loop 3 of Cry1A toxins are important for receptor interaction and toxicity (Rajamohan et al., 1996a; Lee et al., 2001). The Bt-R₁ and the APN epitopes involved in binding loop α -8 and loop 3 regions still remains to be identified.

Cry Toxin-Receptor Binding Function in Toxicity

Three different models of the mode of action have been proposed, the signal transduction model, the pore formation model that involves insertion of monomeric toxin to the membrane before oligomerization and a pore-formation model that involves the formation of a pre-pore oligomer that is responsible for membrane insertion (Zhang et al., 2006; Vachon et al., 2012; Pardo-López et al., 2013). The three models share the initial steps that include protoxin solubilization and activation by gut proteases to release the toxin core.

The signal transduction model was put forward based on the characterization of the death pathway of an insect cell line (H5 cells from *T. ni*) that expressed a cadherin molecule cloned from *M. sexta* larvae, which is a well-known receptor of Cry1Ab toxin (Zhang et al., 2006). The signal transduction pathway that was shown to be involved in cell death included activation of protein G after Cry1Ab binding to cadherin resulting in activation of adenylate cyclase increasing the cellular levels of cAMP. High cAMP levels activate a protein kinase A leading to cell death by oncosis (Zhang et al., 2006). In the signal transduction pathway oligomerization of Cry1Ab toxin and binding other molecules as aminopeptidase-N (APN) or alkaline phosphatase (ALP) is not important for toxin action (Zhang et al., 2006).

The two other models propose that toxicity is exerted by pore-formation that leads to osmotic cell lysis of the midgut cells (Vachon et al., 2012; Pardo-López et al., 2013). However, both models differ in that one model proposes that oligomerization of Cry toxin follows after insertion of monomer toxin to the insect gut membrane while the other model involves oligomerization of the toxin before membrane insertion (Vachon et al., 2012; Pardo-López et al., 2013). The first model proposes that binding of monomeric Cry toxin to any of the characterized midgut receptors as cadherin, APN or ALP is sufficient to facilitate toxin insertion into the membrane (Vachon et al., 2012). This model is supported by the fact that incubation of monomeric toxin with brush border membranes from susceptible insects results in irreversible binding of the monomeric toxin to the membrane (Vachon et al., 2012). This has led to propose that monomers insert into the membrane before toxin oligomerization (Vachon et al., 2012). Nevertheless, it was recently shown that Cry1A toxin is able to form oligomers in solution in the absence of lipid membranes after binding to cadherin (Gómez et al., 2014). Also it was shown that after interaction of monomeric toxin with brush border membranes that contain toxin receptors (including cadherin) the irreversible interaction of the activated toxin with BBMV correlated with insertion of a heat sensitive oligomer into the membrane (Ihara and Himeno, 2008; Gómez et al., 2014), implying that the observed monomers inserted into the membranes are indeed disassembled oligomers that are heat labile (Gómez et al., 2014).

Finally, the third proposed model of the mode of action of Cry1A toxins involves the sequential interaction of Cry1A toxins with different receptor molecules, as GPI-anchored ALP and APN and cadherin protein leading to toxin oligomerization, membrane insertion and pore-formation (Pardo-López et al., 2013). It was proposed that monomeric toxin binds with low affinity to the highly abundant ALP or APN approaching the toxin to the target membrane (Pacheco et al., 2009; Arenas et al., 2010). Then Cry1A monomers bind with high affinity to cadherin facilitating the removal of the N-terminal α -helix 1 by an uncharacterized protease triggering toxin oligomerization (Gómez et al., 2002b; Pacheco et al., 2009). Oligomers bind again ALP and APN with high affinity leading to membrane insertion and pore-formation (Pacheco et al., 2009; Arenas et al., 2010). Domain II exposed loops and Domain III β -16 and β -22 were shown to be involved in the sequential interaction of Cry1Ab toxin with the different receptor molecules (Gómez et al., 2006; Pacheco et al., 2009; Arenas et al., 2010). In favor of this model of the mode of action, Cry1Ab and Cry1Ac were engineered to lack the N-terminal α -helix 1 creating Cry1AMod toxins (Soberón et al., 2007). The Cry1AMod toxins were shown to form oligomers in the absence of cadherin and to counter resistance to *P. gossypiella* Cry1Ac resistant population linked to cadherin mutations. These data shows that cadherin is involved in Cry1A toxin oligomerization and that oligomerization is a key step in Cry1A mode of action (Soberón et al., 2007). Interestingly, Cry1AMod toxins were shown to counter resistance in other insect species where resistance is not linked to cadherin mutations like in *Plutella xylostella* where Cry1Ac resistance is linked to mutations on an ABC2 transporter (Tabashnik et al., 2011).

It was shown that helix α -3 from Domain I is involved in into oligomerization since certain Cry1Ab or Cry11Aa mutations in this region are affect on toxin oligomerization and toxicity to *Manduca sexta* or *Aedes aegypti* respectively showing that oligomerization is necessary for Cry toxicity in different insect orders (Jiménez-Juárez et al., 2007; Muñoz-Garay et al., 2009). Moreover, characterization of Cry1Ab and Cry11Aa α -helix 4 non-toxic mutants showed that these mutations did not affect toxin oligomerization but oligomers were affected in membrane insertion (Rodríguez-Almazán et al., 2009; Carmona et al., 2011). These results show that oligomerization is a prerequisite step in toxin membrane insertion.

In other pore-forming toxins, receptor binding facilitates a complete proteolytic activation of the protoxins resulting in the formation of functional oligomers that re membrane insertion competent (Abrami and Van der Goot, 1999). In the case of Cry1A toxins, the differences of binding affinities between APN and Bt-R₁ (100 nM vs 1 nM K_d respectively) suggest that binding to Bt-R₁ is the first event on the interaction of Cry1A toxins with microvilli membranes.

Evidences that interaction of Cry toxin with its cadherin-like receptor is a necessary step for a complete proteolytic of the toxin were provided (Gómez et al., 2002b). Incubation of Cry1Ab protoxin with the single chain antibody scFv73, that mimics the cadherin-like receptor, and treatment with *M. sexta* midgut juice, resulted in toxin preparations with high pore-formation activity

in vitro in contrast to toxin preparations activated with proteases in the absence of the antibody that showed very poor pore-formation activities (Gómez et al., 2002b). The high pore formation activity correlated with the formation of a 250 kDa oligomer composed of four Cry toxins that lacked the helix α -1 of domain I. The oligomer, in contrast with the 60 kDa monomer, has higher hydrophobicity as judged by 8-anilino-1-naphthalenesulfonate binding (Gómez et al., 2002b). The oligomer was membrane insertion competent in contrast with the monomer as judged by measuring toxin membrane insertion using the intrinsic fluorescence of tryptophan residues (Raussel and Bravo unpublished results). The 250 kDa oligomer structure could also be obtained by incubation of the Cry1Ab protoxin with brush border membrane vesicles, presumably by the action of a membrane associated protease (Gómez et al., 2002b). Therefore the proposed role for cadherin binding is to facilitate the complete proteolytic activation of the toxin and the formation of a pre-pore structure of four monomers. The characterization of the membrane insertion capabilities of the pre-pore, the kinetic characterization of the ionic pore formed by this structure and solving its three-dimensional structure could be important steps towards understanding the role of this insertion-intermediate structure in the mode of action of Cry toxins.

As mentioned previously APN receptors are also key molecules involved in the toxicity of Cry1 toxins. What is the role of APN binding on the mode of action of Cry1 toxins? An indication on its possible role came from the characterization of membrane microdomains (lipid rafts) from microvilli membranes of *M. sexta* and *H. virescens* (Zhuang et al., 2002). Lipid rafts are detergent-insoluble lipid microdomains enriched in cholesterol, sphingolipids, and GPI-anchored proteins (Zhuang et al., 2002). Lipid rafts have been implicated in membrane and protein sorting and in signal transduction (Simons and Toomre, 2000). Also, they have been described as portals for different virus, bacteria and toxins. The interaction of different bacterial toxins with their receptors located in lipid rafts is a crucial step in the oligomerization and insertion of toxins into the membrane (Cabiaux et al., 1997; Abrami and van der Goot, 1999; Rosenberger et al., 2000). Like their mammalian counterparts, *H. virescens* and *M. sexta* lipid rafts are enriched in cholesterol, sphingolipids, and glycosylphosphatidylinositol anchored proteins (Zhuang et al., 2002). Several Cry1A receptors, including the GPI anchored proteins, 120- and 170 kDa APN's from *H. virescens* and the 120 kDa APN from *M. sexta* were preferentially partitioned into lipid rafts. After toxin exposure, Cry1A toxins were associated with lipid rafts and the integrity of these microdomains was essential for *in vitro* Cry1Ab pore forming activity (Zhuang et al., 2002). Therefore the possible role of APN-binding could be to drive Cry1A toxins, probably the pre-pore, to lipid rafts microdomains where the toxin inserts and forms pores. The participation of lipid rafts in the mode of action of Cry toxins could suggest a possible role of signal transduction events and/or the internalization of Cry toxins, since lipid rafts have an active role in these cellular processes. In the case of Cry5 toxin evidence was provided showing that toxin is internalized into the epithelial midgut cells after exposure *C. elegans* nematodes to the toxin (Griffitts et al., 2001).

Binding of Cry1A toxins to cadherin and APN receptors are key steps on the mode of action of these toxins. However, the participation of other uncharacterized molecules on the process of membrane insertion and pore formation of these toxins cannot be excluded. It was proposed that ABCC2 transported could participate in the insertion of the oligomeric structure into the membrane (Heckel, 2012), but this hypothesis requires to be proven. Heterologous expression of the *B. mori* ABCC2 transporter in SF9 cells conferred binding capacity of these cells with the Cry1A toxin and also induced susceptibility to the toxin in toxicity assays suggesting that ABCC2 is a functional receptor of Cry1A toxins (Tanaka et al., 2013). An alternative hypothesis is that ABCC2 may be involved in oligomer formation, this idea was proposed since the Cry1AMod toxins counter resistance to resistant insect populations linked to ABCC2 mutations (Franklin et al., 2009; Tabashnik et al., 2011) and Cry1AMod toxins are able to make oligomers in absence of toxin receptors. Thus, it is possible that in different insects cadherin and ABCC2 may play similar roles.

In an extension of the sequential binding model of toxin action it was reported that Cry1Ab and Cry1Ac protoxins are also able to bind with high affinity cadherin from *M. sexta* or *P. gossypiella* respectively (Fabrick and Tabashnik, 2006; Gómez et al., 2014). In the case of Cry1Ab it was shown that protoxin binding to cadherin in the presence of midgut juice resulted in Cry1Ab oligomerization. Both oligomers, the one formed from activated toxin or the one formed from protoxin are assembled with monomeric toxins as shown by disassembling oligomers by heat treatment (Gómez et al., 2014). The two oligomers are somehow different they can be distinguished by their membrane insertion capabilities, apparent molecular size, heat sensitivity and pore-formation (Gómez et al., 2014). Also, it was shown that both pre-pore oligomers are involved in toxicity of Cry1Ab to *M. sexta* larvae (Gómez et al., 2014). Therefore, it was proposed that two distinct modes of action involving toxin binding or protoxin binding to receptors are involved in Cry1A toxicity. In favor of this dual-mode of action model, it was recently shown that different resistant lepidopteran strains that evolved resistance to Cry1Ac were more sensitive to Cry1Ac protoxin than to activated Cry1Ac toxin indicating that protoxins have an independent pathway to exert toxicity (Tabashnik et al., 2015).

Toxin Insertion

Insertion of Cry toxins into membranes may require a major conformational change in the toxin to expose hydrophobic surface that could interact with the membrane bilayer. Domain I has been recognized as the pore forming domain based on mutagenesis studies (Wu and Aronson, 1992; Cooper et al., 1998), and the similarity of the structure of this domain with other pore-forming domains of bacterial toxins as colicin Ia, diptheria translocation domain and hemolysin (Aronson and Shai, 2001). The α -helices of domain I are long enough to span the membrane and have an amphipathic character (Aronson and Shai, 2001). Helix α -5 is highly hydrophobic and conserved (conserved block 1) among all 3-domain Cry toxin family (de Maagd et al., 2001). Cross-linking experiments done in Cry1Ac mutants that were genetically engineered to create disulphide bridges between some α -helices of domain I showed that domain I swings away from the rest of the toxin exposing α -7 helix for the initial interaction

with the membrane resulting in the insertion of the hairpin formed by α -helices 4 and 5 into the membrane (Schwartz et al., 1997b). Analysis of the insertion capabilities of synthetic peptides corresponding to the seven α -helices of domain I from Cry3A showed that α -helix 1 is the only helix that does not interact with the membrane in contrast to the other helices (Gazit et al., 1998). Helices α -4 and 5 were the only helices capable of adopting a transmembrane orientation (Aronson and Shai, 2001; Gazit et al., 1998). These results suggest that α -helices 4 and 5 insert into the membrane while the rest of the helices remain on the membrane surface. These data agree with the proposed “umbrella model” of toxin insertion in which helices α -4 and α -5 insert into the membrane leaving the rest of the α -helices in the interface of the membrane (Schwartz et al., 1997b). In view of the proposed role of the pre-pore structure in toxin insertion (Gómez et al., 2002b), it is tempting to speculate that in the three dimensional structure of the pre-pore, four α -helices 7 are exposed and form an hydrophobic surface that participates in the initial interaction of the tetramer with the membrane. Following, four hairpins formed by α -4 and α -5 helices inserts into the membrane. The location of domains II-III in the membrane inserted state is unknown. However, with exception of α -helix 1, membrane inserted Cry1Ac toxin resist proteinase K treatment suggesting that domains II-III might be also, somehow, inserted into the membrane (Aronson, 2000).

A different model of the inserted toxin, based on calorimetric determinations, proposed that the three-dimensional structure of the toxin does not change dramatically compared to the structure of the soluble monomer (Loseva et al., 2001). In this model, pore lumen is provided by domain II and domain III residues while domain I hydrophobic surface (without helices α -1 to α -3) faces the lipid bilayer in a oligomeric structure (Loseva et al., 2001). In this regard it is interesting to note that mutagenesis of conserved arginine residues in Cry1Aa domain III affected the characteristics of the pore-formation activity of Cry1Aa toxin suggesting that domain III participates in the channel activity (Schwartz et al., 1997b). Analysis of pore-formation activity of several Cry1 quimeric proteins established that the characteristics of the pore is influenced by domain II and domain III, combination of domain III from Cry1Ab with domains I and II of Cry1C gave a protein that was more active than Cry1C in Sf9 cells. (Rang et al., 1999). Solving the structure of Cry toxins in the membrane inserted state will be important to determine the possible roles of domains II-III in pore-formation.

Analysis of fluorescence spectroscopy of different single Cys Cry1Ab mutants located each one in different regions of Cry1Ab and labeled with different fluorescent probes showed that the three domains of the toxin remain in the surface of the membrane and only a discrete region of domain I, composed by the α -helices 4 and 5 hairpin, is inserted into the lipid bilayer supporting the umbrella model of toxin insertion (Zavala et al., 2011).

Pore Formation

Based on the observation of large conductance states formed by several Cry toxins in synthetic planar lipid bilayers (Lorence et al., 1995; Peyronnet et al., 2002) and the estimation of a pore size between 10 and 20 Å (Von-Tersch et al., 1994), it has been proposed that the pore could be formed by an oligomer of Cry toxins containing four to six toxin monomers. Evidences showing that the intermolecular interaction between Cry1Ab toxin monomers is a necessary step for pore formation and toxicity were provided (Soberón et al., 2000). Two Cry1Ab mutant proteins affected in different steps of their mode of action (binding and pore formation) recovered pore-formation activity and toxicity against *M. sexta* larvae when mixed, showing that monomers affected in different steps of their mode of action can form functional hetero-oligomers and that oligomerization is a necessary step for toxicity (Soberón et al., 2000). Recently, the structure of the pore formed by Cry1Aa toxin was analyzed by atomic force microscopy showing that the pore is a tetramer (Vie et al., 2001). This data is in agreement with the proposition of a pre-pore structure composed of four monomers (Gómez et al., 2002b). The regions of the toxin involved in oligomerization have not been determined, however, based on mutagenesis studies and analysis of toxin aggregation it has been suggested that some residues of α -helix 5 are implicated in this process (Vie et al., 2001; Aronson et al., 1999).

The pore activity of Cry toxins has been studied by a variety of electrophysiological techniques (Schwartz and Laprade, 2000). Pore formation activity of Cry toxins has been studied in synthetic membranes without receptor or in isolated brush border membrane vesicles containing natural receptors (Peyronnet et al., 2001, 2002; Bravo et al., 2002a). As mentioned previously, the presence of receptor (APN) diminished the concentration, more than 100 fold, of Cry1Aa toxin required for pore-formation activity in synthetic planar bilayers (Schwartz et al., 1997a). Cry toxins form pores that are poorly selective to cationic ions including divalent cations (Lorence et al., 1995; Kirouac et al., 2002). High pore conductances are induced by Cry toxins in synthetic planar bilayers (Lorence et al., 1995; Peyronnet et al., 2002). These high conductances are probably related to clusters of various number of identical size pores operating synchronously rather than pore oligomer structures of different sizes (Peyronnet et al., 2002). In contrast to other pore forming toxins, pore-formation activity of Cry1 proteins is not regulated by low pH, suggesting that Cry toxins are not internalized into acidic vesicles for insertion as other pore forming toxins (Tran et al., 2001).

Overall the mode of action of Cry toxins is depicted in Fig. 8 and can be visualized as follows: (1) Crystal solubilization resulting in 130 kDa protoxin; (2) activation of the protoxin by midgut proteases resulting in the monomer 60 kDa activated toxin production; (3) binding of toxin monomer to GPI-anchored receptors, ALP or APN, located in the apical membrane of midgut cells; (4) binding of toxin monomer or protoxin to the cadherin receptor also located in the apical membrane of midgut cells. Conformational change and oligomer formation of a molten globule state of the monomer with exposure of hydrophobic regions; (5) formation of an oligomeric structure; (6) Binding of the toxin oligomer to APN or ALP receptors; (7) mobilization of receptors and Cry toxin to membrane microdomains and insertion into the membrane for pore formation (Fig. 9).

Gene structure of Lepidopteran Cadherin receptors

Heliothis virescens resistant allele

Pectinophora gossypiella resistant alleles

Fig. 9 Gene structure of resistant cadherin-alleles of *Heliothis virescens*. Reproduced from Gahan, L.J., Gould, F., Heckel, D.G., 2001. Identification of a gene associated with Bt resistance in *Heliothis virescens*. Science 293, 857–860. And *Pectinophora gossypiella*. Reproduced from Morin, S., Biggs, R.W., Shriver, L., et al., 2003. Three cadherin alleles associated with resistance to *Bacillus thuringiensis* in pink bollworm. Proc. Natl. Acad. Sci. 100, 5004–5009. Sig corresponds to signal sequence for protein export; CR, cadherin repeat or repeated Ectodomains; MPR, membrane proximal region; TM, transmembrane region and CYT, cytosolic domain. * stands for stop codons; red triangle, transposon insertion and deletions are depicted as solid lines. Red sections on CR 7 and 11 are Cry1A binding epitopes mapped on *M. sexta* Bt-R₁ cadherin receptor.

Synergism of Mosquitocidal Toxins

As previously mentioned Cyt toxins synergies the insecticidal effect of some Cry toxins. *Bacillus thuringiensis* subsp. *israeliensis* (Bti) is highly toxic to different mosquito species like *Aedes* spp., *Culex* spp., *Anopheles* spp. and black fly. (Margalith and Ben-Dov, 2000). This bacterium produces a crystal inclusion composed of at least four toxins: Cry4A, Cry4B, Cry11A and Cyt1A (Guerchicoff et al., 1997). The toxicity of the crystal inclusion is, by far, greater than the toxicity of the isolated Cry and Cyt components. Bti Cry toxins are

Fig. 10 Mechanism of synergism between Cyt and Cry toxins in mosquitoes. Cyt1Aa toxin functions as a membrane bound receptor of Cry11Aa and Cry4Ba facilitating Cry toxin oligomerization and membrane insertion.

more toxic against mosquito larvae than Cyt1A with a difference in toxicity of at least 25-fold (Wirth et al., 1997). However, the Cyt1A toxin synergizes the effect of the other Cry toxins. Toxicity of different combinations of Cry toxins with CytA1 was higher than the addition of expected toxicities of the isolated components (Crickmore et al., 1995; Khasdan et al., 2001). The mode of action of Cyt toxins resembles in some aspects the mode of action of Cry toxins: solubilization of the toxin under the alkaline pH and reducing conditions of the midgut, proteolytic processing of the protoxin, binding of the toxin to the epithelium surface of midgut cells and pore-formation leading to cell lysis (Li et al., 1996, 2001). An important difference between Cyt and Cry toxins is the lack of a protein receptor, Cyt toxins binds phospholipids and are capable of forming pores in cell lines of different origin (Li et al., 1996, 2001). Besides the synergistic effect of Cyt toxins, these proteins overcome or suppress resistance of mosquitoes to the Cry toxins (Wirth et al., 1997). *Culex quinquefasciatus* populations resistant to Cry4A, Cry4B or Cry11A recovered sensitivity when assayed in the presence of Cyt toxin (Wirth et al., 1997). Even more, it has not been possible to select resistant mosquitoes against Cry toxins when selection is performed in the presence of Cyt toxin (Wirth et al., 1997). As mentioned previously, Cyt toxins are principally found in dipteran active strains. However, a coleopteran-active strain containing a Cyt toxin has been described, although the possible synergistic effect of this toxin to other Cry proteins has not been analyzed (Guerchicoff et al., 2001).

The mechanism of synergism of Cyt1Aa and Cry11Aa or Cry4Ba depends on the specific interaction between these toxins since single point mutations on specific epitopes of Cyt1Aa affected Cry11Aa or Cry4Ba binding and synergism (Pérez et al., 2005; Cantón et al., 2011). Also, it was shown that Cry11Aa or Cry4Ba domain II loop regions involved in receptor binding were also involved in binding and synergism with Cyt1Aa (Pérez et al., 2005; Cantón et al., 2011). These data led to the hypothesis that Cyt1Aa functions as a membrane bound receptor of Cry11Aa or Cry4Ba (Pérez et al., 2005; Cantón et al., 2011) (Fig. 10). To enhance the toxicity of Cry11Aa, Cyt1Aa facilitates oligomerization of Cry11Aa as has been shown for cadherin in *A. aegypti* (Pérez et al., 2007). These results indicate that Cyt1Aa is a surrogate receptor of Cry11Aa and Cry4Ba explaining its capacity to counter resistance to these toxins. This is the first example of an insect pathogenic bacterium that carries toxins and also their functional receptor, promoting toxin binding to target membranes and toxicity. Interestingly the Cyt1Aa α -helix C mutants affected in oligomerization still synergize the toxicity of Cry11Aa indicating that membrane insertion is not necessary for the synergistic activity of Cyt1Aa (López-Díaz et al., 2013).

Finally the insect specificity of Cyt2Ab toxin was modified to kill aphids by inserting a peptide sequence in exposed regions of the toxin (Chougule et al., 2013). The peptide sequence was identified by its binding capacity to an aphid APN (Chougule et al., 2013). This suggests that toxicity of Cyt2Ab in aphids is limited by the number of binding sites in the membrane. This is in agreement with the analysis of the mode of action of Cyt1Aa in the non-susceptible lepidopteran *M. sexta* in comparison with *A. aegypti* that showed that toxicity of Cyt1Aa in *M. sexta* is limited by the number of Cyt1Aa binding sites in brush border membranes (Cantón et al., 2014).

Genomics

The genome size of different Bt strains is in the range of 2.4–5.7 million bp (Carlson et al., 1994). Comparison of physical maps with that of *B. cereus* strains suggests that all *B. cereus* and Bt have chromosomes with very similar organization (Carlson et al., 1996). In May 2003 the complete genome sequence of type strains of the close Bt relatives *B. anthracis* (Gene Bank: AE016879) and *B. cereus* (Gene Bank: AE016877) were completed (Read et al., 2003; Ivanova et al., 2003). The *B. cereus* strain ATCC 14,579 strain could be considered a Bt strain based on ribosomal 16S sequence, but does not produce crystals inclusions. 5.427 million bp corresponds to the complete sequenced genome of strain *B. cereus* ATCC 1479 (Ivanova et al., 2003). Analysis of putative coding regions and comparison to the sequence of the *B. anthracis* type strain showed that this group of bacteria lack the capacity of metabolizing diverse types of carbohydrates that characterize typical soil bacteria like *Bacillus subtilis*. Carbohydrate catabolism in the *B. cereus* group is limited to glycogen, and starch, chitin and chitosan (Ivanova et al., 2003). In contrast, *B. cereus*, *B. anthracis*, and presumably Bt, have a wide variety of peptide, amino-acid transporters and amino-acid degradation pathways indicating that peptides and amino-acids may be the most preferred nitrogen and carbon sources for these bacteria. These data led to the speculation that probably the habitat of the common ancestor of the *B. cereus* group was the insect intestine (Ivanova et al., 2003). The presence in the genome of several hydrolytic activities support this speculation, chynolitic activities could participate in the degradation of chitin present in the peritrophic membrane, while the zinc metalloprotease enhancing could degrade the major component of the peritrophic membrane mucin. Also, several genes related to possible invasion, establishment and propagation in the host were identified in both genome sequences (Read et al., 2003; Ivanova et al., 2003). Finally, the analysis of putative PlcR regulated genes gave a figure of 55 "PlcR boxes" controlling over 100 genes including four other transcriptional activators implying that the PlcR regulon is more complex than expected (Ivanova et al., 2003).

Sequence of Plasmid pBtoxis

Bt isolates usually harbor large plasmids, which are self-transmissible, containing δ -endotoxin genes that distinguish them from *B. cereus* strains (Schnepf et al., 1998). Therefore, the sequencing of plasmids containing *cry* genes could help to understand the evolution and spread of *cry* genes in nature. In the year 2002, the complete sequence of a toxin encoded plasmid from Bti (pBtoxis) was released (Berry et al., 2002). One hundred twenty eight kilobases were sequenced. This plasmid contains 125 putative coding sequences with an average gene length of 725 bp (Berry et al., 2002). Sequence analysis showed that besides the known Cry toxins genes (*cry4Aa*, *cry4Ba*, *cry11A*, *cry10Aa*, *cyt2Ba*, *cyt1Aa*) a putative novel *cry* gene was identified. Based on phylogenetic relationships with other Cyt toxins, the novel gene was named *cyt1Ca* (136). In contrast to the Cyt toxins, Cyt1Ca, contains an additional domain located on the C-terminus (280 residues) that shares similarity with domains present in other bacterial toxins that are involved on carbohydrate recognition (Berry et al., 2002). Therefore it was proposed that Cyt1Ca could be recognizing carbohydrate moieties in the cell surface (Berry et al., 2002). Based on sequence analysis, 8 pseudogenes were identified. Among these, several gene fragments that shared significant sequence identity to described *cry* genes were identified, suggesting that the ancestors of plasmid pBtoxis contained other *cry* genes that were lost afterwards (Berry et al., 2002). Interestingly the *cry* gene fragments are located nearby transposon related sequences indicating that gene transposition may have caused these genetic rearrangements and could be an important mechanism for toxin-gene spread and evolution (Berry et al., 2002). Beside *cry* genes, plasmid pBtoxis contains several putative genes coding for virulence factors (Berry et al., 2002). A second *plcA* gene, coding for phosphatidyl-inositol phospholipase C, was identified. However, this gene is probably not translated and no "PlcR box" was found in the promoter region of this gene. Interestingly, a "PlcR box" was identified in front of a peptide antibiotic production and export system, this peptide antibiotic may be a novel virulence factor (Berry et al., 2002). Other genes related to sporulation and germination were identified, suggesting that plasmid could influence the sporulation and germination of the host strain (Berry et al., 2002). An interesting feature of plasmid pBtoxis is that it shares similarity with a limited number of genes of plasmid pXO1, the virulence plasmid of *B. anthracis*; 29 of 125 open reading frames show amino acid sequence similarity to open reading frames present in pXO1 (Berry et al., 2002).

Mechanism of Insect Resistance

One of the major concerns regarding the use of Bt is the generation of insect populations resistant to Cry toxins. Resistance to Cry toxins could be obtained by interfering any of the steps involved on the mode of action of Cry toxins. The analysis of the molecular mechanism of insect resistance to Bt toxins have been mostly based on the study of insect resistant populations selected in the laboratory. These studies could provide knowledge leading to design rational procedures for resistant management in nature. However, resistance mechanisms of natural insect populations are likely not to compromise significantly the fitness of the insects to guarantee the fixation of resistant mutant alleles in the population. Therefore, the mutant alleles found on laboratory selected insect populations may not necessarily be found in nature although alleles found in nature could be present in laboratory selected lines.

Selection of insects resistant to Bt toxins in the laboratory has been performed for a variety of insect species. *Lepidopteran* insects resistant to Bt toxins include, *Plodia interpunctella*, *Plutella xylostella*, *Heliothis virescens* and *Spodoptera exigua* (Ferré and Van Rie, 2002). Coleopteran insects species include *Leptinotarsa decemlineata* and *Chrysomela scripta* (Ferré and Van Rie, 2002). As mentioned above, selection of Cry toxin resistant dipteran insects has been performed for *Culex quinquefasciatus* (Wirth et al., 1997). Finally resistance to Cry toxins has also been achieved for the, non-insect, nematode *C. elegans* (Griffitts et al., 2001). Different insect species have developed resistance to Cry toxins in nature, such as the diamondback moth (*P. xylostella*) to Bt- spray applications (Ferré and Van Rie, 2002) and at least 6 different insect species to different Bt-crops, *Spodoptera frugiperda* resistant to Cry1Fa-corn in Puerto Rico and Brazil (Storer et al., 2010; Farias et al., 2014), *Busseola fusca* resistant to Cry1Ab-corn in South Africa (Van Rensburg, 2007), *Pectinophora gossypiella* resistant to Cry1Ac-cotton in India (Dhurua and Gujar, 2011), *Helicoverpa zea* resistant to Cry1Ac-cotton (Tabashnik et al., 2008) and *Diabrotica virgifera virgifera* resistant to Cry3Bb-corn in the USA (Gassmann et al., 2011).

Resistance to Cry toxins can evolve by blocking any of the steps of the mode of action. Following, we will summarize recent findings on the mechanisms involved in resistance to Bt toxins.

Proteolytic Activation

As mentioned previously Cry protoxins are activated by the action of midgut proteases. A Bt toxin-resistant line of *P. interpunctella* had lower protease and protoxin activating activities. These differences were shown to be due to the lack of a major trypsin-like proteinase in the gut. Genetic analysis showed a co-segregation of the lack of the major protease and insect resistance to Cry1Ab toxin (Oppert et al., 1997). The consequence of reduced gut protease was a lower concentration of the activated toxin in the gut (Oppert et al., 1997). The resistant strain showed altered growth and morphology suggesting that in particular this allele is unlikely to be selected in natural populations.

Receptor Binding

The most frequent mechanism of resistance to Cry toxins is defects on receptor binding (Ferré and Van Rie, 2002). Different *Lepidopteran* resistant populations from different species show an effect on toxin binding (Ferré and Van Rie, 2002). In a *P. interpunctella* strain selected for resistance to Cry1Ab, toxin binding affinity (K_d) was reduced 50-fold. Interestingly, this strain

showed an increased susceptibility to Cry1C toxin that correlated with an increase number of binding sites to this toxin (Ferré and Van Rie, 2002). In the case of four *P. xylostella* strains that developed resistance in the field, reduced Cry1A binding correlated with resistance (Schnepf et al., 1998; Ferré and Van Rie, 2002).

In the case of the laboratory selected *H. virescens* Cry1Ac-resistant line YHD2 it was shown that a single mutation was responsible for 40%–80% of Cry1Ac resistance levels. The mutation was mapped and shown to be linked to a retrotransposon insertion in the cadherin-like gene (Gahan et al., 2001). As mentioned previously, this result shows that binding of Cry1A toxins to cadherin-like receptors is an important event in the mode of action of these toxins. Based on these results, the group of Tabashnik suggested that if mutations of cadherin genes are the primary basis of resistance in the field, the characterization of cadherin-alleles could be helpful in monitoring field resistance (Morin et al., 2003). The characterization of cadherin alleles in field-derived and laboratory selected strains of the cotton pest *Pectinophora gossypiella* (pink bollworm) revealed three mutated cadherin alleles that were associated with resistance in this lepidopteran insect (Morin et al., 2003).

Resistance has been associated or linked to mutations that affect receptor expression or production. Examples of resistance to Cry1Ac linked to cadherin gene mutations have been shown in *Heliothis virescens* (Gahan et al., 2001), *Pectinophora gossypiella* (Morin et al., 2003) and *Helicoverpa armigera* (Xu et al., 2005). In the case of field-evolved resistance of *Pectinophora gossypiella* in India to Cry1Ac-cotton it was shown that resistance was associated with different cadherin allele mutations (Fabrick et al., 2014). Resistance associated with low ALP or APN expression has been documented in *Trichoplusia ni* (Tiewisiri and Wang, 2011), *H. armigera* (Zhang et al., 2009) or *H. virescens* (Jurat-Fuentes et al., 2002, 2011) to Cry1Ac and also in *S. frugiperda* to Cry1F-Cotton (Jurat-Fuentes et al., 2011) or in *S. exigua* to Cry1Ca (Herrero et al., 2005). In recent years a novel mechanism of resistance to Cry1Ac in different lepidopteran species was shown to be linked to mutations in an ABC2 transporter gene (Heckel, 2012). ABC transporters mediate the import or export of molecules against their concentration gradient by coupling transport to ATP hydrolysis (Heckel, 2012). Resistance linked to ABC2 mutations have been characterized in *H. virescens* (Gahan et al., 2010), *Plutella xylostella* (Baxter et al., 2011), *T. ni* (Baxter et al., 2011) and *Bombix mori* (Atsumi et al., 2012). In the case of *T. ni* and *P. xylostella* resistance associated with ABC2 mutations was evolved in field conditions in response to Bt formulations (Tabashnik et al., 1994; Janmaat and Myers, 2003). The precise role of ABC2 in Cry1A toxin mode of action is not understood but expression of *B. mori* ABC2 gene in insect cell line conferred binding and susceptibility to Cry1A toxins suggesting that ABC2 is a functional receptor of Cry1A toxins (Tanaka et al., 2013). In the case of *B. mori* resistance to Cry1Ab toxin was linked to a single tyrosine insertion in a predicted exposed loop region suggesting that this loop may be a binding site for Cry1Ab toxin (Atsumi et al., 2012).

Oligosaccharide Synthesis

As mentioned previously, domain II and domain III of Cry toxins show structural similarity to carbohydrate binding domains and in the case of Cry1Ac toxin, binding to the APN receptor involves carbohydrate moieties (de Maagd et al., 1999a; Burton et al., 1999). Nevertheless, the most compelling evidence of the involvement of carbohydrate moieties on the mode of action of Cry toxins came from the selection and characterization of nematode *C. elegans* Cry5B-resistant lines (Griffitts et al., 2001). Five independent *C. elegans* resistant strains were selected by feeding with *E. coli* cells expressing Cry5B toxin. Cloning and sequence of one gene responsible for the resistant phenotype (*bre-5*) showed that the mutated gene shares high sequence similarity to β -1,3-galactosyltransferase enzyme involved in carbohydrate synthesis (Griffitts et al., 2001). The *bre-5* mutation also confers resistance to the Cry14A toxin that also has been shown to be toxic to insects (Griffitts et al., 2001). *bre-5* mutation had no effect on the fitness of the resistant nematodes (Griffitts et al., 2001). These results suggest that carbohydrate moieties could be important in the mode of action (probably binding) of some Cry toxins.

In the case of the *H. virescens* YHD2 Cry1Ac-resistant line, an altered pattern of glycosylation of two microvillar proteins of 63 and 68 kDa was shown to correlate with resistance (Jurat-Fuentes et al., 2002). As mentioned above, YHD2 strain contains several mutations responsible for its Cry1Ac-resistant phenotype. Although the most important resistant allele is the disruption of the cadherin-like gene, altered glycosylation of microvilli membrane proteins increases its resistant phenotype (Jurat-Fuentes et al., 2002).

Applications of Cry Toxins

Forestry

One of the most successful applications of Bt has been the control of *Lepidopteran* defoliators pests of coniferous forests mainly in Canada and United States. Strain HD-1, producing Cry1Aa, Cy1Ab, Cry1Ac and Cry2Aa toxins, has been the choice for controlling forests defoliators. Use of Bt for the control *Choristoneura fumiferana* (Spruce worm) started in the mid 1980s (Van Frankenhuyzen, 2000). Afterwards Bt has been used for the control of *Ch. pinus pinus* (Jackpine budworm), *Ch. occidentalis* (Western spruce worm), *Lambdina fiscellaria fiscellaria* (Eastern hemlock looper) *Lymantria dispar* (gypsy moth) and *Orgyia leucostigma* (whitemarked tussock moth) (Van Frankenhuyzen, 2000). In Canada, for the control of spruce worm, up to 6 million hectares have been sprayed with Bt while up to 2.5 million hectares have been sprayed for the control of other defoliators. In the case of United States up to 2.5 million hectares have been sprayed with Bt. In these countries, the control of forests defoliators relies 80%–100% on the use of Bt. In Europe, Bt use for the control of defoliators greatly increased in the 1990s reaching up to 1.8 million hectares of forests treated

with Bt (van Frankenhuyzen, 2000). Successful application of Bt for the control of defoliators is highly dependent of proper timing, weather conditions and high dosage of spray applications. These factors combine to determine the probability of larvae ingesting a lethal dose (Van Frankenhuyzen, 2000). The use of Bt in the control of defoliators has resulted in a significant reduction on the use of chemical insecticides for pest control in the forests.

Control of Mosquitoes and Black Flies

As mentioned previously, Bti is highly active against disease vector mosquitoes like *Aedes aegypti* (vector of dengue fever) *Simulium damnosum* (vector of Onchocearciasis) and certain *Anopheles* species (vector of malaria). The high insecticidal activity, the lack of resistance to this Bt subspecies, the lack of activity to other organisms and the appearance of insect resistant populations to chemical insecticides made a fast development of Bti as an alternative control method of mosquitoes and black flies populations.

In 1983, very soon after the discovery of Bti, a control program for the eradication of Onchocearciasis was launched in eleven countries of Western Africa since the *Simulium damnosum* populations developed resistance to the larvicidal organophosphate (Guillet et al., 1990). Now days, more than 80% of the region is protected by Bti applications and 20% with temephos (Guillet et al., 1990). The disease has been controlled protecting over 15 million children without the appearance of resistance to Bti (Guillet et al., 1990).

In the Upper Rhine Valley in Germany, Bti along with *B. sphaericus*, has been used to control *Aedes vexans* and *Culex pipiens pipiens* mosquitoes. Each year, approximately 300 river kilometers and 600 km² inundation areas are treated with Bti. Since 1981, more than 170,000 hectares of mosquito breeding sites have been treated with different Bti formulations. This program (KABS) has resulted in the reduction of mosquito populations by over 90% each year (Becker, 2000). These results are comparable to the use of Bti for the control of *Aedes vexans* in the United States of America and in Southern Switzerland (Becker, 2000). Again, no resistance to Bti has been observed after more than 20 years of the launch of the program (Becker, 2000).

High Malaria incidences in Hubei Province in China were reduced by more than 90% by the application of Bti and *B. sphaericus* into the Yangtze River. The vector mosquitoes *Anopheles sinensis* and *Anopheles anthropophagus* populations were reduced 90% by weekly applications of fluid formulations of two Bti and *B. sphaericus* strains (Becker, 2000). In Brazil the outbreak of *A. aegypti* resistant populations to chemical insecticides in Rio de Janeiro and Sao Pablo led to the application of Bti formulations for mosquito control (Regis et al., 2000).

The success of vector control using Bti will certainly spread the use of this Bt subspecies around the world. Still the low activity of Bti to certain vector mosquitoes will require the isolation of novel strains with novel cry genes effective against different disease vectors.

Transgenic Crops

Bt is the leading biopesticide used in agriculture. However only 2% of the insecticidal market is cover by Bt sprayable products, the rest is cover mostly by chemical insecticides (Navon, 2000). Since the discovery of the HD-1 strain, formulations for lepidopteran pests control were released. Now days Bt products for the control of coleopteran insects are also available. However, the higher costs of commercial Bt products than chemical insecticides, lower efficacy of Bt compared to chemical insecticides, the limited persistence of Bt products and the narrow insect spectrum limited the number of crops on which Bt is used for plant protection. Moreover, sucking and borer insects are poorly controlled by the spray of Bt products (Navon, 2000).

The creation of transgenic crops that produce crystal Bt proteins has been a major break through on the substitution of chemical insecticides by environmental friendly alternatives. In transgenic plants Cry toxin is produced continuously protecting the toxin from degradation and making it reachable to sucking and borer insects. Cry protein production has been improved by engineering cry genes with a codon usage compatible with that of plants, by removal of putative splicing signal sequences and deletion of the c-terminal region of the protoxin (Schuler et al., 1998). In the year 1995 the first Bt-crop (Bt-potato) was commercialized. These transgenic plants expressed the Cry3A protein for protection against Colorado potato beetles resulting in 40% reduction in insecticidal use in the year 1997 (Schuler et al., 1998). In the year 1996 Bt-cotton, producing the Cry1Ac toxin, was released to protect cotton from tobacco budworm, cotton bollworm and pink bollworm. Also in the year 1996 Bt-maize, producing Cry1Ab toxin, was released for the control of European corn borer larvae (Schuler et al., 1998). In the year 2000, transgenic crops were grown on 44.3 million hectares globally. Of this, 23% were insect resistant Bt-maize and 74% were herbicide resistant crops (James, 2001). Yield effects of insect resistant crops in USA are less than 10% on average, nevertheless use of insect resistant crops has diminished considerably the use of chemical pesticides (Qaim and Zilberman, 2003). However, the use of Bt-cotton in countries like China, Mexico and India showed that the use of this Bt-crop had a significant effect on yields and also in the use of chemical pesticides since in underdeveloped countries yield loss is mainly due to technical and economical constrains which are overcome in part by the use of insect resistant crops (Qaim and Zilberman, 2003; Toenniessen et al., 2003).

Recently the pyramided expression of Vip3A with Cry1Ab in Bt- plants have shown that this practice increases the efficacy of insect control of some pests such as *H. zea*, *O. nubilalis* and *S. frugiperda* (Burkeness et al., 2010). In addition, the binary toxin Cry34/Cry35 was expressed alone or in combination with Cry3Bb in corn plants showing efficient control of *D. virgifera* larvae. Hybrids containing both events received less root damage than a single trait, supporting that pyramided traits is a viable strategy for delaying resistant to individual traits (Prasifka et al., 2013).

Public Concerns on the Use of Bt-Crops

Three major concerns have been raised on the use of Bt-crops: Insect resistance, a direct effect on non-target insects and transgene flow to native landraces.

The large scale introduction of Bt-crops endangers the durability of Bt as insecticide in crops and in sprays since continuous exposure to Bt-plants will lead to selection for Cry toxin resistant insect populations. In response to this threat, resistance management strategies associated with the release of Bt-crops have been developed. The predominant approach involves the combination of high production levels of the Cry protein with the establishment of refuge zones (de Maagd et al., 1999b; Conner et al., 2003). Refuges are areas of non-transgenic crops that are within close proximity of the Bt-plants. This procedure aims to maintain a population of susceptible insects that contain wt alleles. In most cases studied, resistance to Cry toxins is conferred by recessive mutations (Ferré and Van Rie, 2002; de Maagd et al., 1999b; Conner et al., 2003). Thus mating of homozygotes individuals with susceptible alleles with heterozygotes individuals with a resistant allele will give rise to heterozygotes susceptible progeny, delaying the development of resistance. Also, second generation transgenic-crops are now being developed that produce two different Cry proteins that bind to different receptor molecules in the same insect. Thus, the possibility of selecting mutation affected on receptor-toxin interaction are diminished exponentially (de Maagd et al., 1999b).

The massive spray of Bt for forest defoliators raised concern on the effect of Bt toxins on non-target insects (Scriber, 2001). More recently, public concerns over the impact of Bt-crops on non-target insects scaled up based on results obtained on the toxicity of Bt-maize pollen on the Monarch butterfly (Losey et al., 1999). Pollen from a commercial variety of Bt-maize (N4640) expressing *cry1Ab* gene in the whole plant including pollen, spread onto milkweed leaves (*Asclepias syriaca*), was lethally toxic to Monarch butterfly caterpillars in the laboratory (Losey et al., 1999). However, follow-up studies showed that low expression of Bt toxin genes in pollen of most commercial transgenic hybrids, lack of toxicity at expected field rates, no overlap of pollen shed and larval activity and the limited overlap in distribution of Bt-maize and milkweed, made field risk to the Monarch populations negligible (Gatehouse et al., 2002; Hellmich et al., 2001; Oberhauser et al., 2001; Pleasants et al., 2001; Sears et al., 2001; Stanley-Horn et al., 2001; Zangerl et al., 2001).

Concerns were raised about the effects of transgene introduction, or gene flow, on the genetic diversity of crop landraces and wild relatives in areas of crop origin. In the year 2001 Quist and Chapela (UC Berkeley) reported the presence of transgenic DNA (from Bt-maize) constructs in native maize landraces in Oaxaca, México (Quist and Chapela, 2001). Oaxaca is consider part of the Mesoamerican center of origin and diversification of maize. Transgenic DNA was identified by PCR based methodology, the 35S promoter sequence was found in five of seven different Criollo maize samples analyzed (Quist and Chapela, 2001). Moreover, inverse PCR reactions of genomic DNA of native landraces showed a high frequency of transgene insertion into a range of genomic contexts (Quist and Chapela, 2001). Nevertheless, based on criticisms on the interpretation of the data and possible false priming in the PCR reactions (Metz and Futterer, 2002; Kaplinsky et al., 2002), *Nature* reconsider its previous judgment on the acceptability of the results reported by Quist and Chapela and concluded that the evidence provided was not sufficient to justify publication (Editor *Nature*, 2002). Independent studies carried out by the Mexican government (National Institute of Ecology, INE and National Commission of Biodiversity, Conabio) claim to have evidences of the presence of transgenic DNA in native maize landraces although publication of these results is still pending. In any case, gene flow is not restricted to transgenic plants but naturally selected hybrids could also impact the populations and gene content of native landraces. Even if gene flow is confirmed, further studies on the possible impact of the gene flow from commercial hybrids (transgenic or non-transgenic) to native landraces should include long term studies on the integrity of the transgenic constructs (or genes from non-transgenic hybrids) and the maintenance of these genes in the native landraces. These studies should provide a rational framework for taking decisions regarding the introduction and commercialization of transgenic crops in center of origin and diversification of crops. The final goal should be to assure the use of this environmental friendly technology without affecting the genetic diversity of natural landraces.

Glossary

Archaea One of the three domains of living organisms: archaea, bacteria, and eukarya. Although archaea share a basic morphology with bacteria and they are also prokaryotes (*i.e.*, they lack a true nucleus); in many molecular details they resemble eukaryotes more than bacteria. Previously called archaebacteria.

Cell membrane A phospholipid bilayer that surrounds all cells. Also called cytoplasmic membrane or plasma membrane.

Cell wall The tough envelope surrounding many cells, including nearly all bacteria and archaea. Located outside the cytoplasmic membrane.

Channel proteins Proteins that form aqueous pores or channels through membranes.

Crystalline surface layer A surface layer (S-layer) of some bacteria and archaea consisting of protein arrays, usually quite resistant to chemicals and proteases.

Domain (1) A discrete, independently folded region of a protein. Different subfunctions of a multidomain protein are usually localized in separate domains. (2) One of the three major taxons: bacteria, archaea, or eukarya.

Electron transport chain The sequential oxidation/reduction of compounds embedded in a membrane that creates proton/sodium gradients across membranes.

Facilitated diffusion Movement of molecules across a membrane from higher to lower concentration mediated by proteins that permit the passage of specific molecules only.

Glycerol ether lipid A type of lipid, characteristic of the archaea, containing isoprenoid lipids that are ether linked to glycerol.

Gram-negative bacteria A group of bacteria with cell envelopes composed of two membranes, the inner and the outer, lipopolysaccharide-containing membranes as well as thin peptidoglycan cell wall layers.

Gram-positive bacteria Two groups of bacteria, both with thick peptidoglycan cell layers. One group, the low G+C Gram-positive bacteria, lacks an outer membrane. The other, the high G+C Gram-positive 'acid-fast' bacteria, has a thick outer cell membrane overlying the cell wall.

Lipid A A phosphorylated glycolipid common to all Gram-negative bacterial lipopolysaccharides.

Lipopolysaccharides Major components of the outer monolayers of the outer membranes of most Gram-negative bacteria. Abbreviated LPS.

Lipoprotein A protein containing covalently bound fatty acids.

Mycolic acid A long-chain organic acid found in the waxy cell envelope of mycobacteria and related acid-fast high G+C Gram-positive bacteria.

Outer membrane The outer lipid bilayer of many prokaryotes and some eukaryotic organelles. In Gram-negative bacteria, they consist of an outer lipopolysaccharide leaflet and an inner phospholipid leaflet plus proteins. In high G+C Gram-positive bacteria, the outer membranes incorporate mycolic acids.

Passive transport Diffusional passage of a compound across a membrane.

Permease A proteinaceous system functioning in the transport of specific substances through a membrane.

Phospholipid bilayer A membrane consisting of two leaflets, each composed of phospholipid.

Proton motive force (PMF) Potential energy stored in the form of an electrochemical gradient of protons across a cell or organellar membrane.

Secondary active transport Active transport of substances using the sodium or proton motive force as the energy source driving substrate accumulation or efflux.

Sodium motive force (SMF) Potential energy stored in the form of an electrochemical gradient of sodium ions across a cell or organellar membrane.

Symbiosis The living together of two different kinds of organism in a nonharmful fashion.

Symport The coupled movement of two molecules together across a cell membrane. Usually, the concentration gradient of one of them drives the movement of the other.

Abbreviations

ATP	Adenosine triphosphate
CMC	Cytoplasmic membrane
DMSO	Dimethyl sulfoxide
GTP	Guanosine triphosphate
KDO	keto deoxy octulosonate
LPS	Lipopolysaccharides
OM	Outer membrane
OMP	Outer membrane protein
PEP	Phosphoenolpyruvate
PIM	Phosphatidylinositol mannoside
PMF	Proton motive force
SAM	Sorting and assembly machinery
SMF	Sodium motive force
Tat	Twin arginine targeting/translocating
TCDB	Transporter Classification Database
TMAO	Trimethylamine <i>N</i> -oxide
TMS	Transmembrane segment
UDP-GlcNAc	Uridyl-diphospho- <i>N</i> -acetylglucosamine

Defining Statement

In addition to cytoplasmic membranes, shared by all living cells, many prokaryotes possess protective outer membranes that have compositions very different from those of their inner membranes as well as from those of the outer membranes of other organismal types. This article describes these membranes.

Introduction

Bacterial cytoplasmic membranes (CMs) consist primarily of amphipathic phospholipids with lesser amounts of glycolipids. In the case of Gram-negative bacterial outer membranes (OMs), phospholipids are present in the inner leaflet of the bilayer while lipopolysaccharides (LPS) predominate in the outer leaflet. Most Gram-positive bacteria lack an OM. This is true of almost all low G+C Gram-positive bacteria, called ‘firmicutes’, although acid-fast, high G+C Gram-positive bacteria, such as *Mycobacterium* species, have mycolic acid-containing OMs that are structurally very different from the OMs of Gram-negative bacteria. Like Gram-positive bacteria, most archaea lack an OM, but recent studies have revealed the occurrence of archaea with these structures. The lipid constituents of both the inner and OMs of archaea are very different from those of bacteria. The OMs of all of these organisms provide a degree of protection from toxic substances, not found in organisms having a single membrane.

Almost all bacterial membranes are assembled in bilayers with embedded integral and associated peripheral membrane proteins. Lesser amounts of carbohydrates (glycolipids and glycoproteins) extend outward from these membranes. Properties of bacterial membrane proteins and lipid–protein interactions have been studied in detail as have those of archaeal membranes. The latter unique membranes often consist of hydrophobic tails linked by ether rather than ester bonds to the glycerol-containing lipid backbone. A few archaea have complex envelopes which, like those in some bacteria, consist of inner and outer membranes that are of different lipid and protein contents.

Our understanding of prokaryotic cell membrane dynamics has advanced considerably since the fluid mosaic model was proposed by Singer and Nicolson in 1972, and links between CM structure and function have been extensively elucidated. Lipid and protein membrane compositions are central to survival since prokaryotes in general are subject to extreme physical and chemical stresses. The CM should be thought of as the primary boundary between the external environment and the living cell while the OM serves a primary protective function. Flexibility in the adaptive capacity of the envelope and its components to environmental conditions is a primary determinant of cell survival.

The selectively permeable envelope allows appreciable diffusion of small neutral molecules such as H₂O, NH₃, CO₂, and O₂, although transport proteins may increase diffusional rates or allow accumulation against concentration gradients. However, this envelope presents high-energetic barriers to the permeability of moderately sized and large polar molecules. The CM serves the cell in numerous capacities providing functions including active transport, macromolecular synthesis, energy generation, maintenance of electrochemical gradients, and cell division.

Membrane Fluidity

Microbial membranes provide a fluid matrix for embedded proteins. The membrane state is frequently defined in terms of degree of fluidity. Fluidity reflects the lipid order and microviscosity which in turn are determined by lipid shape and packing. A composite measure of the lateral and rotational movement of lipids seems to determine membrane lipid phase behavior.

Static as well as dynamic properties are characteristic of all biological membranes. Changes in CM fluidity may reflect physical and chemical interactions with environmental factors such as temperature, pH, osmotic pressure, internal and external ion compositions, and the presence or absence of various chemicals. Membrane perturbations elicit adaptive responses that must compensate for suboptimal conditions. Membrane alterations represent only one type of response, but these membrane responses, required to maintain cell function, guarantee a degree of fluidity that allows transmembrane transport as well as lateral lipid and protein diffusion without jeopardizing membrane stability.

Lipids exhibit polymorphism; each lipid has a distinctive headgroup and two dissimilar fatty acids. They aggregate into different structures such as bilayers and micelles, and assume structurally distinct phases. In a bacterial cell, integral membrane proteins largely exist in the bilayers of the cell, but a smaller portion of these proteins are present as small micelles with a range of phospholipids layered on the hydrophobic belt of the protein, replacing the bilayer. The phases of a bilayer depend on forces including exclusion volume, headgroup interactions, and van der Waals interactions between hydrocarbon chains. Lipid behavior within bacterial membranes is complicated by the huge variety of lipid types present. This diversity makes lipids among the most flexible and versatile of the various types of biological macromolecules.

The dynamic phase behavior of membranes balances the gel-to-liquid crystalline and the lamellar-to-nonbilayer phase transitions. Cumulative evidence suggests that mechanisms of cellular homeostasis are integrated elements of the dynamic range of membrane behavior. Methods used to study fluidity include X-ray diffraction, differential scanning calorimetry, electron spin resonance, nuclear magnetic resonance using ^2H or ^{31}P , and fluorescence polarization. Visualization of the membrane has been achieved by electron microscopy and X-ray diffraction. Fluorescence polarization and several of the other cited methods can be used to measure the static versus dynamic characteristics of the membrane. The first of these techniques has the advantage that it can be used with viable bacteria under a variety of normal and stressed conditions as well as *in vitro* with isolated membrane preparations.

Molecular studies have revealed the types of lipid order and phase alterations employed by prokaryotes to maintain CM fluidity and function. The use of extracted bacterial and archaeal lipids has revealed differences of *in vitro* versus *in vivo* properties resulting from membrane adaptations. CM polarization data for bacteria have been obtained under normal and a variety of environmental stress conditions, revealing the responses of membranes to these conditions.

Bacterial CMs

The CM of any bacterium is an $\sim 80\text{-}\text{\AA}$ -thick structure separating the interior of the cell from the environment. It prevents the diffusion of most substances into and out of the cytoplasm and acts as a selective barrier to concentrate metabolites and nutrients within the cell while secreting waste products and toxins. These structures will be reviewed here while OM of bacteria will be described in the sections titled 'Gram-negative bacterial OM' and 'OM of acid-fast Gram-positive bacteria'. Archaeal membranes will be discussed in the section Archaeal membranes.

Structure, Composition, and Function of CMs

The CMs of most bacteria consist of roughly equal amounts of phospholipid and protein (see Fig. 1(a)). They contain $\sim 70\%$ of the cellular phospholipids and 25% of the cellular proteins. The phospholipids are amphipathic, having hydrophobic tails and hydrophilic heads. The glycerol backbone contains two bound fatty acids and a phosphoryl headgroup. Three major types of phospholipids are present in *Escherichia coli*, about 2×10^7 molecules per cell: 75% phosphatidylethanolamine, 20% phosphatidylglycerol, and 5% cardiolipin (diphosphatidylglycerol). All of these phospholipids contain α -glycerol-phosphate esterified with fatty acids at the one and two positions. The predominant fatty acids in *E. coli* are palmitic acid (16:0), palmitoleic acid (16:1), and *cis*-vaccenic acid (18:1). Different bacteria have different ratios of these lipids, and many have others as well. Sterols, glycolipids, amino acid-containing lipids, and other hydrophobic and amphipathic molecules can be present, depending on the species.

The CM is stabilized by hydrophobic interactions and hydrogen bonds; the former are also known as van der Waals interactions. In addition, divalent cations such as Mg^{2+} and Ca^{2+} stabilize the membrane by neutralizing the negative charges of the phospholipids on both sides of the bilayer, serving as 'salt bridges'. The asymmetric bilayer, with different lipid and protein compositions for the two apposed monolayers, is thus a stable structure that serves as an encapsulating 'bubble' for the cell cytoplasm.

As noted above, the fatty acid composition of the phospholipids that comprise the CM (*e.g.*, chain length, substitutions, and degree of saturation) are determined during biosynthesis, dependent on internal and environmental conditions such as stage of growth, temperature, and composition of the external milieu. The CM maintains a fluid state to allow conformational flexibility and lateral diffusion of proteins and protein complexes. Fluid membranes also have higher transmembrane permeabilities to small molecules than do more rigid bilayers. As noted above, the phospholipids occur primarily in a bilayer, forming a hydrophobic barrier, but micellar structures and 'lipid rafts' of unusual composition may be present, illustrating their dynamic nature.

Fig. 1 (a) Schematic view of the *Escherichia coli* cell envelope. Lipopolysaccharide (LPS), embedded within and extending from the outer surface of the outer membrane, consists of three moieties: lipid A, core polysaccharide, and the O-antigen polysaccharide side chains. A trimeric porin in the outer membrane and integral membrane proteins in the inner membrane are depicted schematically. The peptidoglycan cell wall in the periplasm separates the two membranes. (b) Structure of the *E. coli* lipopolysaccharide (LPS) showing the sugar residues. KDO, keto deoxy octulosonate; Hep, heptose; Glc, glucose; Gal, galactose; NAG, *N*-acetylglucosamine; Rha, rhamnose; Man, mannose; Abe, abequose; *n*, a variable number of repeat units.

The membrane prevents the unregulated transmembrane movement of polar molecules and allows the selective retention of ions, essential metabolites, and macromolecules. Due to the presence of specific transport systems, it also catalyzes the active extrusion from the cell of end products of metabolism, drugs, and toxins.

Integral membrane proteins in the CM are anchored into the membrane with one or more transmembrane segments (TMSs). Others, peripheral membrane proteins, are loosely bound and interact transiently, often due to ionic attractive forces. Analyses of the *E. coli* protein content (the proteome) indicate that about one quarter of the predicted gene products are integral membrane proteins in the CM. Many are critical for cellular functions (e.g., transport and cell division). The largest functional class is the transport proteins which comprise 5%–15% of the total proteome, depending on the organism. Owing to their hydrophobic and amphiphilic characters, membrane proteins are much more difficult to study than soluble (cytoplasmic and extracellular) proteins. They account for less than 2% of the known high-resolution protein structures, solved by either X-ray crystallography, multidimensional nuclear magnetic resonance, or cryo-electron microscopy. Topological models have been derived that depict the number of TMSs and the orientation of the proteins in the lipid bilayer, and in numerous cases, these structural predictions have been verified experimentally. However, in relatively few cases do we know how the various TMSs interact with each other to form compact, functional proteins and protein complexes.

Amino acid residues of the portions of proteins that are embedded in the membrane have hydrophobic character, as do residues in the cores of soluble proteins. Residues in the same membrane proteins that are exposed to the aqueous environment, however, are much more polar. Residues in membrane proteins that are exposed to lipid acyl side chains have greater hydrophobic character than do residues in the protein interior. The latter are often semipolar and are important for maintaining correct conformation of the lipid bilayer. In general, TMSs in the CM are hydrophobic α -helices.

In addition to transport, CM proteins can be involved in transmembrane electron flow, energy generation and conservation, biosynthesis of hydrophobic substances, synthesis of cell envelope constituents, and translocation of cell wall and envelope macromolecules from the inside of the cell to an extracytoplasmic locale. This last mentioned function can include translocation and insertion of proteins through and into the one or two membranes of the bacterial cell envelope. Thus, there are at least five compartments in the Gram-negative bacterial cell: the cytoplasm, the inner membrane, the periplasm between the two membranes, the OM, and the extracellular milieu. Moreover, in both membranes, the inner and outer leaflets of these bilayers can be considered as distinct compartments. Specific, dissimilar, and evolutionarily distinct protein insertion complexes are responsible for integration of inner and outer membrane proteins (OMPs) into the envelope. It is also important to note that certain bacteria have been shown to possess a variety of membrane-bounded organelles such as magnetosomes which allow bacteria to orient in the Earth's magnetic

field, chromatophores where photosynthesis occurs, gas vacuoles that provide the function of flotation, and sulfur granules that house elemental sulfur. The complexity of the prokaryotic cell is thus far greater than was initially believed.

Energy Generation and Conservation

Many biosynthetic and CM transport processes are driven by the hydrolysis or transfer of the high-energy phosphoryl moieties of adenosine triphosphate (ATP), guanosine triphosphate (GTP) or phosphoenolpyruvate (PEP). In many cases, the phosphoryl group is transferred transiently to a protein or solute, whereas in a few other cases, phosphoryl bond hydrolysis drives the formation of high-energy protein conformational states; yet other transport processes are energized by transmembrane ion gradients. Cells growing under fermentative conditions, in the absence of oxygen or another inorganic electron acceptor, produce ATP by substrate-level phosphorylation reactions as in the glycolytic pathway. Generally, bacteria that generate energy primarily by substrate-level phosphorylation (fermentation) use ATP or PEP to drive the majority of their transport processes, whereas bacteria that generate energy primarily *via* electron transfer (respiration) use ion (proton and sodium) gradients to drive most of their transport processes. In the former case, the ATP synthesized by substrate-level phosphorylation can also be used to form transmembrane ion gradients by using the F_1F_0 proton-translocating ATPase, while ion gradients generated *via* respiration can be used to synthesize ATP in the reverse process catalyzed by the same enzyme complex. Marine bacteria more frequently use Na^+ gradients to drive transport than observed for fresh water or terrestrial bacteria.

For cells growing under respiratory conditions, the passage of electrons through an electron transfer chain to suitable electron acceptors (oxygen, fumarate, nitrate, nitrite, dimethyl sulfoxide (DMSO), trimethylamine *N*-oxide (TMAO) or hydrogen (H_2)), can be coupled to the extrusion of protons or sodium ions and the creation of transmembrane electrochemical gradients. The resultant proton motive force (PMF, $\Delta\mu_{H^+}^+$) or sodium motive force (SMF, $\Delta\mu_{Na^+}^+$) is essential for life and can be used to drive transport. However, the transmembrane electrochemical gradient is also important in maintaining protein conformations, opening channels, and influencing transmembrane enzyme activities.

Bacterial respiratory chains consist of a series of physically separate protein complexes. Commonly, membrane-bound dehydrogenases transfer two electrons and/or hydrogen atoms from their substrates to the pool of quinones. Electron donors in bacteria include reduced molecules such as NADH, succinate, α -glycerol phosphate, nitrite, and sulfides. Quinones serve as mobile hydride carriers diffusing through the membrane. These quinones shuttle reducing equivalents from the dehydrogenases to terminal reductases or oxidases that oxidize the electron acceptors listed in the preceding paragraph. While ubiquinone-8 is the predominant quinone species in aerobically grown *E. coli* cells, menaquinone-8 is the major species in cells grown anaerobically. Several, but not all of these respiratory/electron transfer complexes, catalyze proton or sodium ion export during electron flow. This proves to be one of the primary mechanisms for generating ion motive forces (the PMF and SMF).

Translocation of Proteins

Integral CM proteins need to be integrated into the membrane, and hydrophilic proteins need to be translocated through the CM from the inside of the cell where they are made, to the external cell surface where they function. For these purposes, the general secretory (Sec) pathway and the twin arginine targeting/translocating (Tat) pathway which act on unfolded and folded proteins, respectively, are usually used. A protein, YidC, assists insertion of proteins into the CM, alone or in conjunction with the Sec pathway. Especially in Gram-negative bacteria, but also in other prokaryotes, other protein complexes are integrated into the CM, working in conjunction with outer-membrane complexes destined to secrete proteins into the medium. Altogether, 18 distinct protein insertion/secretion systems have been identified in Gram-negative bacteria: nine each for transport across or into the inner and outer membranes, respectively. Some of these systems translocate their protein substrates across the two membranes in a single energy-coupled step (See the Transporter Classification Database (TCDB; www.tcdb.org)).

Solute Transport

Nonpolar substances such as fatty acids, neutral alcohols, and simple aromatic compounds enter and exit the cell to some extent by dissolving in the lipid bilayer. By contrast, charged molecules such as organic acids and inorganic salts must be specifically transported. Water penetrates the membrane fairly freely, being small and uncharged, but aquaporins may facilitate the process, allowing more rapid water fluxes than would otherwise be possible in response to osmotic stress conditions. Similarly, passage of NH_3 and CO_2 through the membrane can be stimulated by the presence of 'gas channels'. Most polar molecules are transported *via* specific membrane transporters, but there are many different types and hundreds of families of these proteins as tabulated in the Transporter Classification Database (TCDB). Active transport mechanisms allow the accumulation and extrusion of solutes against concentration gradients, while facilitated diffusion merely allows the energy-independent equilibration of the substrate across a membrane.

Most solutes are transported across prokaryotic CMs by energy-dependent mechanisms, and prokaryotes possess a remarkable array of active transport systems. These systems usually exhibit high substrate affinity and stereospecificity; the affinities reflect the concentrations of the solutes in the natural environments of these organisms. Mechanisms of energy-coupling to transport include: symport with and/or antiport against ions, ATP or GTP hydrolysis, phosphoryl transfer from phosphoenolpyruvate to sugar substrates (group translocation), organic acid decarboxylation, methyl transfer, light absorption, and electron flow. Group

translocation involves the simultaneous transport and modification of substrates, often involving the expenditure of phosphoryl bond-type energy.

Gram-Negative Bacterial OMs

Gram-negative bacteria, and some Gram-positive bacteria, and archaea are surrounded by OMs which serve as selective permeation barriers. They prevent the entry of noxious compounds while allowing the influx of nutrients. They contain β -structured porins and other proteins that allow selective permeability and catalyze specific reactions. These membranes in Gram-negative bacteria will be considered in this section. Those in Gram-positive bacteria will be discussed in the section titled 'OMs of acid-fast Gram-positive bacteria', and those in archaea will be considered in the section titled 'Archaeal membranes'.

Structure and Composition of the OM

The OMs of most Gram-negative bacteria are asymmetric lipid bilayers where the inner leaflet contains phospholipids while the outer leaflet contains a preponderance of LPS (Fig. 1(a) and (b)). Gram-negative bacteria lacking LPS may instead have sphingolipids and/or various glycolipids. These bilayers show low permeability to many solutes. Amino acids, most vitamins, short peptides, sugars, *etc.*, can cross the OM by diffusion through porin channels if smaller in mass than 600 Da. These channel proteins form β -barrel structures with transmembrane spanning segments consisting of amphipathic antiparallel β -strands. α -Helical proteins in the OMs of these organisms are rare, just as are β -structured proteins in the inner membranes. β -Barrel porins, in general, do not concentrate their substrate solutes across the membrane; they catalyze facilitated diffusion.

Other compounds such as vitamin B₁₂ and iron siderophore complexes use substrate-specific, high-affinity active transporters to cross the OM. The energy required to allow these transporters to accumulate their substrates in the periplasm is derived from a complex of proteins (*e.g.*, TonB, ExbB, and ExbD in *E. coli*) that use the PMF across the inner membrane to energize uptake. Since these receptors are exposed to the cell surface, infective agents such as some colicins and bacterial viruses (phage) can parasitize TonB-dependent systems or their homologues to enter and kill the host bacteria. Exactly how these protein complexes accumulate their substrates in the periplasm of the Gram-negative bacterial cell and allow passage of toxic proteins or DNA from phage into the cell is still an intense area of research.

The OMs of Gram-negative bacteria contain at least five major classes of proteins: (1) structural lipoproteins, (2) membrane-integrated β -barrel porins, (3) solute-specific receptors, (4) membrane-anchored enzymes, and (5) multicomponent surface structures such as fimbriae (organelles of adhesion), pili (organelles of conjugation or twitching motility), and flagella (organelles of motility). Lipoproteins usually have lipids and/or fatty acids covalently attached to an N-terminal cysteine. These tails, embedded in the OM, anchor these proteins within the membrane. β -Barrel proteins consist of β -sheets that are wrapped into cylinders. Many of these proteins (the porins referred to above) form channels allowing the free flow of nutrients and waste products. Porins can be nonspecific or specific for a particular class of substrates. Nonspecific porins act as 'molecular sieves', but the more specific porins may restrict permeation to a class of sugars, amino acids, ions, or other nutrient types. β -Barrel proteins may also possess enzymatic activities such as hydrolase activities. Moreover, as mentioned in the preceding paragraph, receptor proteins, embedded in the OMs *via* β -barrel structures, can accumulate their solutes in the periplasm against considerable concentration gradients using the PMF across the CM to drive uptake.

OM Lipopolysaccharides

LPSs (Fig. 1(a) and (b)) are found uniquely in most Gram-negative bacterial OMs. They are composed of three parts: the proximal, hydrophobic lipid A region which is embedded in the outer leaflet of the OM; the distal, hydrophilic O-antigen polysaccharide region that protrudes into the medium; and the core oligosaccharide region that connects lipid A to the O-antigen repeat units (Fig. 1(a)). Lipid A is a polar lipid of unusual structure in which a backbone of glucosaminyl- β -(1 $\rightarrow$ 6)-glucosamine is substituted with six or seven saturated fatty acyl residues.

In *E. coli*, LPS biosynthesis begins in the bacterial cytoplasm with the acylation of uridyl-diphospho-*N*-acetylglucosamine (UDP-GlcNAc) with β -hydroxymyristate. After deacetylation, the product of this reaction is further modified with a second β -hydroxymyristate to generate UDP-2,3-diacylglucosamine. Cleavage of the pyrophosphate bond and displacement of the nucleotide, UMP, produces 2,3-diacylglucosamine-1 phosphate. After condensation of this compound with another molecule of UDP-2,3-diacylglucosamine and 4' phosphorylation, the intermediate, lipid A, is formed. Two keto deoxy octulosonate (KDO; 3-deoxy-D-manno-oct-2-ulosonic acid) residues are then transferred, and two acyltransferases add lauroyl and myristoyl groups (Fig. 1(b)). The core sugar residues are added onto this intermediate, and an export system translocates them from the cytoplasmic side to the periplasmic surface of the CM. The O-antigen, which is assembled and polymerized separately, is added in the periplasm, completing the biosynthetic process (Fig. 1(b)). Subsequent transport reactions probably move the LPS molecules across the periplasmic space into the inner leaflet and finally to the outer leaflet of the OM (Fig. 1(a)). Lipid A is the biologically active component of LPS which causes inflammation and septic shock in animals.

Three kinds of LPS modifications have been observed: (1) substitution of the phosphate groups in lipid A with phosphoethanolamine, (2) decoration of the basic structure with additional sugar residues, and (3) addition of palmitate by esterification.

Derivatization with phosphoethanolamine renders the bacteria resistant to a lipid A-binding, cyclic, cationic peptide antibiotic, polymyxin, while palmitoylation provides resistance against cationic antimicrobial peptides induced by the innate immune system in response to bacterial infections. These modifications may occur alone or in combination on a single LPS molecule, yielding multiple LPS species in a single bacterium.

Gram-negative bacteria produce OM blebs or vesicles of 0.5–1.0 μm in diameter. These vesicles that can contain enzymes and signaling molecules are released into the culture medium to be delivered to other bacteria, where the vesicles again fuse to the OM of the recipient bacterium. These vesicles can also be used to deliver bacterial protein toxins to mammalian cells. They provide a novel mechanism of prokaryotic communication.

OM Proteins

OMPs are usually synthesized in the bacterial cytoplasm as precursors with N-terminal signal peptides and are translocated, often co-translationally, across the CM *via* the general Sec pathway. After removal of the signal peptides by a signal peptidase, many of the mature proteins insert into the OM and assume β -barrel structures with hydrophobic, membrane-embedded outer surfaces suitable for interaction with LPS and membrane lipids. The insertion process is mediated by a complex of proteins called the BAM complex where Bam A serves as the outer membrane receptor and translocator (see OMP insertion). OM proteins can be classified based on their functions: (1) lipoproteins, (2) general porins, (3) substrate-specific receptors, (4) enzymes, and (5) various other OM proteins.

Lipoproteins

Dozens of lipoproteins have been described. The murein lipoprotein, Lpp of *E. coli*, is the most prominent and best-studied member. Lpp is a small protein (7200 Da) present in about a million copies per cell. Its N-terminal cysteine is modified at two sites. The cystearyl sulfhydryl group is substituted with a diglyceride, and the α -amino group is derivatized by a fatty acyl residue. This allows penetration into and anchoring to the inner leaflet of the OM. About one-third of these molecules are bound covalently to the underlying peptidoglycan cell wall layer, thereby attaching the OM to the wall. Deletion of the *lpp* gene results in numerous defects such as leakage from the periplasm, increased susceptibility of the cell to toxic compounds, and increased blebbing of membrane vesicles from the OM with the release of vesicles into the external milieu. These lipoproteins thus serve important structural roles.

Porins

Porins allow the diffusion of fairly small hydrophilic (and occasionally hydrophobic) molecules. They exhibit varying degrees of substrate specificity. They can be nonspecific or show selectivity only for the charge of the substrate, either anionic or cationic. Some are even specific for certain types of molecules – oligosaccharides, peptides, amino acids – or anions. They generally form OM water-filled channels. Many are either monomeric or homotrimeric, the latter being formed by three hollow β -barrels. However, other quaternary porin structures have been reported. They can be small or large, having 8–24 transmembrane β -strands per polypeptide chain, and they frequently have extra hydrophilic protein domains on one or both sides of the membrane. Their pore sizes vary; several of their three-dimensional structures have been determined, allowing visualization of the permeation pathway. A conspicuous structural feature is the presence of an ‘eyelet’ region, a narrow constriction in the pore, lined with charged residues. These charged residues determine in part the specificity of the porin for the substrates.

As an example, the trimeric phosphoporin, PhoE of *E. coli*, is produced under conditions of phosphate starvation. The channel-forming motif of PhoE is a 16-strand antiparallel β -barrel. Short β -hairpin turns define the periplasmic side of the barrel, whereas long irregular loops are found at the cell surface. PhoE functions primarily in anion transport due to the presence of positively charged residues near the mouth of the channel. OMPs probably fold in the periplasm before being inserted into the OM in the presence of LPS. The insertion of proteins into these membranes is generally poorly understood, but it depends on a multicomponent protein insertion apparatus which is essential for the process (see ‘OM protein insertion’).

Substrate-Specific Receptors

While most nutrients gain access to the periplasm by diffusion through porins, a few substrates are too large to enter by this route. Large receptor/transport systems form energy-dependent gated channels which take up these compounds. The TonB/ExbB/ExbD type systems energize transport using the PMF- and TonB-dependent receptors. Examples of such receptors in *E. coli* include BtuB for vitamin B₁₂ uptake and several receptors for the uptake of different iron–siderophore complexes. Iron–siderophore complexes are high-affinity iron chelators of microbial origin. Transport requires an interaction with the periplasmic protein TonB, which may shuttle between the inner and outer membranes. The action of TonB requires an energized CM in the form of a PMF. Energy is transferred to the receptors with the assistance of the two cytoplasmic H⁺ channel-forming membrane proteins ExbB and ExbD, which energize TonB by transporting protons down their electrochemical gradient, across the CM. Energized TonB then transmits its energy to the receptors.

These siderophore receptors and BtuB are β -barrel monomeric proteins that consist of 22 transmembrane β -strands each. The N-terminal domain consists of a globular structure that inserts itself into the barrel from the periplasmic side, forming a plug. Binding of a ligand induces a conformational change in the protein so that the most N-terminal portion containing a short motif, called the 'TonB box', can interact with the TonB protein. This first step is followed by a large-scale conformational change caused by the energized TonB. The molecular details of this process are not yet fully understood.

OMP Insertion

Gram-negative bacterial OMPs are assembled from the periplasm into the OM in a process that is a current area of research. Large (~800 aas) OMPs, complexed with several others, play a crucial role. These bacterial proteins are very distantly related to the chloroplast import-associated channel proteins, IAP75, constituents of the chloroplast envelope protein translocase. IAP75 has been shown to be a β -barrel porin in the OM of plant chloroplasts. Another homologue is the yeast mitochondrial sorting and assembly machinery (SAM) constituent, SAM50. The SAM complex in yeast mitochondria consists of at least three proteins and is required for the assembly of OM β -barrel proteins in mitochondria. It seems clear that these organellar protein complexes were derived from bacterial proteins when endosymbiotic α -proteobacteria and cyanobacteria became permanent residents of eukaryotic cells as mitochondria and chloroplasts, respectively.

The functionally characterized homologue in the Gram-negative bacterium *Neisseria meningitidis*, Omp85, is essential for bacterial viability. It has a two-domain structure with an N-terminal periplasmic domain rich in hydrophilic repeat sequences and a C-terminal domain that forms an integral OM β -barrel. Unassembled forms of various OMPs accumulate when Omp85 is depleted. Homologues of Omp85 are present in all Gram-negative bacteria examined, but not in other prokaryotes. The *E. coli* homologue functions as a principal constituent of a complex that catalyzes protein insertion into the OM.

Normally OMPs are translocated into the periplasm *via* the Sec translocase. They are believed to fold in the periplasm before being inserted into the OM. Folding is stimulated by small periplasmic chaperone proteins. In *E. coli*, these chaperones feed a substrate protein to the OM integrated multiprotein BAM (β -barrel assembly machinery) complex required for OM biogenesis. The activities of the constituents of this system are absolutely required for proper OMP assembly. In fact, the BAM complex functions to insert both outer membrane β -barrel proteins such as porins and outward facing lipoproteins. The BAM complex consists of five proteins that form a heteromeric complex. These five constituents are Bam A, B, C, D and E. Bam A is a large multi domain transmembrane protein that serves as the primary receptor and channel. The channel has a lateral "gate" between the first and last β -strands (β -TMSs1 and 18) in the barrel, allowing a β -strand in a substrate protein to escape into the OM lipid bilayer. BamB – E, on the other hand, are peripheral membrane proteins that facilitate the folding and insertional events.

OMs of Acid-Fast Gram-Positive Bacteria

Acid-fast actinobacteria belong to a distinctive suprageneric actinomycete taxon, which includes mycobacteria, corynebacteria, nocardia, rhodococci, and other related genera. All of these bacteria share the property of having an unusual cell envelope composition and architecture (Fig. 2(a)). Based on available published data, the envelope layers consist of a typical CM of phospholipid and protein, a characteristic wall of unusual structure, and a complex outer layer. Although studies with mycobacteria are more detailed than with other related genera, it is evident that the envelopes of these bacteria are all similar, especially in terms of ultrastructure and cell-wall composition.

The cell walls are formed by thick *meso*-diaminopimelic acid-containing peptidoglycan layers covalently linked to arabinogalactan. The arabinogalactan is in turn esterified with long-chain α -alkyl, β -hydroxy fatty acids. These fatty acids in mycobacteria are called mycolic acids (Fig. 2(b)). They possess very long chains (C_{60-90}) and may contain various branches, oxygen functions such as hydroxyl, methylated hydroxyl, and keto groups as well as unsaturations. Mycolic acids found in other actinomycetes consist of mixtures of saturated and unsaturated acids, but they contain shorter chains. Nocardiomycolic acids are of length C_{40-50} while corynomycolic acids are of C_{22-36} . Thus, mycobacterial OMs are thicker than nocardial OMs which, in turn, are thicker than corynebacterial OMs.

Acid-fast high G+C Gram-positive microbes share with Gram-negative bacteria the property of possessing OMs that are very different in composition from the plasma membranes. While the outer barrier in Gram-negative bacteria is a typical bilayer of phospholipid and LPS, in mycobacteria, nocardia, and corynebacteria, the cell wall-linked mycolates comprise much of this barrier. The lengths and structures of mycolic acids are important in determining not only the membrane width, but also the envelope fluidity and permeability. The existence of OM diffusion barriers in actinobacteria is reinforced by the characterization of cell envelope proteins with pore-forming abilities. The outer permeability barrier consists primarily of a monolayer of mycoloyl residues covalently linked to cell wall arabinogalactans (Fig. 2(a)). Other lipids may be arranged in an outer leaflet to form a complex asymmetric bilayer.

Freeze-fractured samples of mycobacteria and other related bacteria have revealed details of the envelope structures of these organisms with distinct lipid domains. Freeze-fracture electron microscopy also revealed the presence of ordered arrays on the surfaces of these envelopes consisting of surface layer proteins (S-layers) that overlie the OMs. There may therefore be five layers: (1) the inner CM, (2) the cell wall, (3) the arabinogalactan/arabinomannan polysaccharide layer, (4) the OM, and (5) the external proteinaceous S-layer. All have protective functions.

The five layers of the actinobacterial envelope are believed to be integrated to form the protective envelope. Because the amounts of cell wall-linked mycolates are insufficient to cover the entire bacterial surface, other types of noncovalently bound lipids must play

Fig. 2 (a) The most important structural components of the mycobacterial cell envelope. While small hydrophobic molecules may diffuse through the outer lipid bilayer, small hydrophilic molecules require the involvement of outer membrane porins as indicated at the top of the diagram. The figure illustrates the covalent linkages between cell wall peptidoglycan, arabinogalactan, and mycolic acids. (b) Structures of mycolic acids in *Mycobacterium tuberculosis*. α -Mycolates: the meromycolate chains contain two *cis*-cyclopropanes; methoxymycolates: their meromycolate chains contain an α -methyl-ether moiety in the distal position and a *cis*-cyclopropane or an α -methyl *trans*-cyclopropane in the proximal position; ketomycolates: their meromycolate chains contain an α -methyl ketone moiety in the distal position and proximal functionalities as in the methoxy series. Unsaturations are present in some meromycolate chains of *M. tuberculosis* (not shown).

roles in forming the OM. In fact, these lipids have been shown to form bilayer structures spontaneously. Thus, the cell wall permeability barriers in these bacteria involve both covalently wall-linked mycolates and noncovalently bound lipids. These molecules together with various proteins comprise the bulk of the cell envelopes.

OMs of Mycobacteria: Function, Structure, and Composition

As noted above, the permeability of mycobacteria, and other bacteria related to them, to substances in their environments is determined by the properties of their envelopes. Current models depicting the structural organization of the mycobacterial cell wall

assume that peptidoglycan and arabinogalactan strands overlie the CM forming horizontal layers beneath perpendicularly oriented mycolic acids. The mycolate layer prevents entry of small hydrophilic molecules which gain access to the cell only *via* porins (Fig. 2(a)). Some small lipophilic molecules may diffuse through the lipid layer. The capsule prevents passage of virtually all macromolecules unless specific transport systems mediate their entry or exit. The structure of the outer lipid barriers is similar in all mycobacteria, but the capsule is more abundant in slow-growing species than in fast-growing species. The slow-growing organisms comprise the group that includes most mycobacterial pathogens.

Mycobacteria secrete proteins that are important to the pathogenesis of the many human and animal diseases caused by these microbes. Information about how the secreted proteins and the polysaccharides of the capsule cross the outer lipid barrier is fragmentary and is only now coming to light. It is possible that proper knowledge of mycobacterial envelope permeability will enable new approaches to the treatment of mycobacterial diseases.

The cell envelopes of mycobacteria substantially contribute to their resistance to therapeutic agents. This is largely due to the presence of the C_{60–90} mycolic acids that are covalently linked to the large arabinogalactans as well as the acylated and nonacylated arabinomannans. Recent studies have clarified the unusual structures of arabinogalactans as well as extractable cell wall lipids such as phenolic glycolipids, glycopeptidolipids, and trehalose-based lipooligosaccharides called ‘cord factor’. Most of the hydrocarbon chains of these lipids assemble to produce the exceptionally thick, asymmetric OM. Structural considerations suggest that the fluidity is unusually low in the innermost parts of the bilayer, gradually increasing toward the outer surfaces. Differences in mycolic acid structure may affect the fluidity and permeability of the bilayer and explain the different sensitivities of various mycobacterial species to lipophilic compounds. Hydrophilic nutrients, vitamins, minerals, toxins, and growth inhibitors, in contrast, traverse the OM exclusively *via* porin channels.

The detailed molecular structures of representative mycobacterial cell envelopes and their lipids are illustrated in Fig. 2(a) and (b). The cell wall architecture resembles a massive ‘core’ comprised of peptidoglycan covalently attached *via* a linker unit (1-Rha-D-GlcNAc-P) to a linear galactofuran. This in turn is attached to several strands of a highly branched arabinofuran, which is attached to mycolic acids. The mycolic acids are perpendicularly oriented relative to the plane of the membrane (Fig. 2(a)). They create a lipid barrier responsible for many of the physiological, disease-inducing, and drug resistance properties of *Mycobacterium tuberculosis*, *leprae*, *bovis*, *avium*, and other mycobacterial pathogens.

Intercalated within this envelope are the lipids that have intrigued biochemists for over five decades: the phthiocerol dimycocerosate, cord factor (dimycolyltrehalose), the sulfolipids, the phosphatidylinositol mannosides (PIMs) and others. The lipomannans and lipoarabinomannans also play important roles in the physiology and pathogenesis of mycobacteria. These molecules have functions of signaling to the host and stimulating immune responses of infected humans and animals. Mycolic acids are recognized by CD1-restricted T-cells, and antigen 85 – one of the most powerful protective antigens of *M. tuberculosis* – is a mycolyltransferase. Moreover, lipoarabinomannans, when ‘capped’ with short mannose oligosaccharides, promote phagocytosis of the bacteria by animal cells, an important phase of pathogenesis.

Sequencing of the *M. leprae*, *M. tuberculosis* and other pathogenic and nonpathogenic mycobacterial genomes has aided efforts to define the biosynthetic pathways for all of these exotic lipid and complex carbohydrate-containing molecules. These include mycolic acids, the mycocerosates, phthiocerol, lipidated arabinomannans and arabinogalactans, and the polyprenyl phosphates. We now know that synthesis of the entire core is initiated on a decaprenyl-P with synthesis of linker units. There seems to be concomitant extension of the galactan and arabinan chains while these intermediates are transported through the CM. The final steps in these events, the attachment of mycolic acids, and ligation to peptidoglycan, must occur in the periplasm.

Mycolic Acids and Other Unusual Mycobacterial Lipids

As noted above, mycolic acids of mycobacteria are long-chain fatty acids, many of which vary in size and structure (Fig. 2(b)). Arabinogalactan mycolates are covalently linked *via* phosphodiester linkages to the underlying peptidoglycan cell wall polymer (Fig. 2(a)). Mycolic acids together with other cell wall lipids (trehalose-based lipooligosaccharides, phenolic glycolipids, and glycopeptidolipids) comprise part of the OM and contribute to the low permeability of these envelopes. They account in part for the remarkable drug resistance of mycobacteria rendering treatment of mycobacterial diseases difficult. This is particularly important to human health since one-third of the world’s population is infected with mycobacteria, and millions die from mycobacterial diseases every year. The hydrophobic hydrocarbon chains of these lipids comprise the OMs which may be the thickest of all biological membranes yet identified. The asymmetric OM consists largely of long-chain mycolic acids comprising most of the inner leaflet with a diversity of other lipids contributing to the outer leaflet.

Some lipids and lipidated glycans unique to mycobacteria appear to be present in both the inner and the outer membranes. These are the PIMs, their hypermannosylated derivatives, lipomannans, and lipoarabinomannans. They are important virulence factors in pathogenic species. These facts reveal a surprising degree of lipid diversity in mycobacterial envelopes and show that fatty acyl esters linked to complex carbohydrates contribute to the rigidity of these structures.

Mycobacterial OMPs

OMPs of mycobacterial species are far less well characterized than those of Gram-negative bacteria; however, substantial progress has been made. The most important observations are summarized here.

Lipoproteins

The availability of complete genome sequences of mycobacterial species has greatly facilitated the identification of OM lipoproteins. The occurrence of genes encoding these lipidated proteins in the reduced-size genome of *M. leprae* provides a guide to the minimal mycobacterial gene set. Surprisingly, perhaps, these lipoproteins are superficially similar to those of Gram-negative bacteria.

The consensus sequence at the N-terminal region of these proteins includes the cysteine residues to which the lipid moiety becomes attached. This sequence provides clues for the identification of these proteins. More than 20 potential lipoprotein genes have been identified in the *M. leprae* genomic sequence. Lipoprotein LpK, for example, encodes a 371 amino acyl precursor protein which becomes lipidated after it is synthesized, exported from the cytoplasm and proteolytically processed. The purified lipoprotein induces production of interleukin-12 (IL-12) in humans. This implies that LpK is involved in protective immunity against leprosy. The pursuit of such lipoproteins is likely to reveal details of the pathogenesis of a variety of mycobacterial diseases.

Mycobacterial OM Porins

Pore proteins in Gram-negative bacterial OMs that span the membrane mediate the diffusion of small hydrophilic nutrients such as sugars, amino acids, anions, cations, and vitamins (see 'Porins'). *M. tuberculosis* possesses at least three porins, one which is the low-activity NH_4^+ secretion channel protein, OmpATb. OmpATb is essential for adaptation of *M. tuberculosis* to low pH and survival in macrophage. The channel activity of oligomeric OmpATb probably plays a role in the defense of *M. tuberculosis* against acidification within the phagosomes of macrophage. While the C-terminal domain is similar to that of *E. coli* OmpA, the N-terminal channel-forming domain has an $\alpha + \beta$ sandwich class fold unlike the fold of β -barrel porins of Gram-negative bacteria. There is still controversy regarding the porin activity of OmpATb.

Another porin, MspA, is the main porin of the related, fast-growing, nonpathogenic species *M. smegmatis*. It forms a tetrameric and an octameric complex with the former having a central pore of 10 nm length and a cone-like structure. This structure is entirely different from that of the trimeric porins of Gram-negative bacteria suggesting that these two porin types evolved independently. In agreement with this conclusion, MspA shows no significant sequence similarity with any of the Gram-negative bacterial OMPs. The decreased numbers of porins in acid-fast bacteria compared with Gram-negative bacteria and the increased lengths of mycobacterial pores are two primary determinants of the low permeabilities of outer mycobacterial membranes to small hydrophilic solutes. Slow transport through porins needs to be considered when designing novel drugs against mycobacterial diseases.

All actinobacteria with mycolic acid-containing OM contain porins that allow passage of nutrients, salts, and other small molecules across the OM as noted above. Several of these, in addition to those cited above, have been identified and characterized. Some are very small, the smallest being only 37 amino acyl residues in length, but it forms oligomeric pore structures. Others are much larger. Surprisingly, it appears that all or most of these porins contain transmembrane α -helical structures rather than the β -barrel structures found in Gram-negative bacteria. Future studies will reveal if this observation proves to be generally applicable to the actinobacteria. If so, it clearly suggests the actinobacterial porins evolved independently of those in Gram-negative bacteria. By extrapolation, and in view of their very different hydrophobic lipid compositions, it seems reasonable to suggest that outer membranes in these two groups of bacteria evolved independently of each other.

Compartmentalization of Lipid Biosynthesis in Mycobacteria

The plasma membranes of *Mycobacterium* species are the sites of synthesis of several distinct classes of lipids. Some of these lipids are retained in the inner membrane while others are exported to the overlying cell envelope. Enzymes involved in the biosynthesis of different major lipid classes, the PIMs and aminophospholipids, for example, are compartmentalized within the CM and the cell wall containing envelope fractions. Enzymes involved in the synthesis of early PIM intermediates are localized to a plasma membrane subdomain, while later stages of synthesis seem to be associated with external parts of the envelope. This suggests that like the LPSs in Gram-negative bacteria, complex outer envelope lipids may be synthesized in several stages that occur in different compartments of the cell envelope.

Molecular Action of Antimycobacterial Agents

There is evidence that many drugs exert their antimycobacterial activities by interacting with classical bacterial proteinaceous targets. This possibility is supported by both direct and indirect evidence. Mechanistic studies have been performed for drugs such as fluoroquinolones, macrolides, rifampicin, and streptomycin. Although the modes of action of many agents with antimycobacterial activities are not well understood, it seems likely that many drugs will prove to inhibit specific molecular targets involved in the biosynthesis of mycobacterial cell envelope constituents such as its many unique lipids and carbohydrate polymers. The recent reemergence of tuberculosis as an important human pathogen has prompted the development of improved methods for exploring the structures, biochemistry, and genetics of mycobacterial envelopes. These advances should be useful in gaining a better understanding of the molecular basis of drug action in mycobacteria.

Archaeal Membranes

Archaea are similar to bacteria in many aspects of cell structure, but they differ radically with respect to the lipid compositions of their membranes (Fig. 3(a) and (b)). The structures of their cell surfaces and their protein, lipid, and carbohydrate constituents are also unique. Archaeal membranes contain glycerol ether-linked isoprenoidal lipids rather than ester-linked fatty acyl lipids as are found in bacteria and eukaryotes (Fig. 3(b)). Only the archaeal lipids are based on isoprenoid side chains. In addition, bacterial-type peptidoglycan cell walls are altogether lacking, and in their place, cell walls consisting of surface layer proteins are present (Fig. 3(a)). OMs are not found in the better-characterized archaea, although they have been identified in one class of these organisms and are probably present in others. Because the existence and the unique properties of these organisms have been recognized for a relatively short period of time, much less is known about the OMs of archaea than about those of Gram-negative and acid-fast Gram-positive bacteria as well as those of eukaryotic organelles.

Archaeal Lipids

Polar ether lipids of archaea account for 80%–90% of the total membrane lipids in these organisms. The remainder are neutral squalenes and other isoprenoids. Many such unique lipids have been discovered in recent years. Genus-specific combinations of various lipid core structures include diether-tetraether, dietherhydroxydiether, and diether-macrocyclic diether-tetraether lipid moieties. The basic structure of a representative archaeal ether lipid and its comparison with a bacterial eukaryotic ester lipid are shown in Fig. 3(b).

Fig. 3 (a) A typical archaeal cell illustrating the positions and structural features of the ether-linked lipids in the cytoplasmic membrane. The illustrated membrane is a 'blow-up' of the archaeal cell as visualized by electron microscopy. (b) Structure of an archaeal ether lipid (top) compared with that of a typical bacterial ester lipid (bottom). Primary structural differences are illustrated.

Some archaeal species have only the standard diether core lipids. None is known with predominantly tetraether lipids. The relative proportions of these lipid cores are known to vary with growth conditions in some archaea such as *Methanococcus jannaschii* and *Methanobacterium thermoautotrophicum*. The ether-linked isoprenoids can exist as either monolayers or bilayers. Polar head-groups in glycosidic or phosphodiester linkage to glycerol consist of polyols, other carbohydrates, or amino compounds. These lipid structures have been shown to provide protection from extreme temperatures, pH values, and a range of salinities. Recently, a radical S-adenosylmethionine (SAM) protein in *Sulfolobus acidocaldarius* has proven to be required for the synthesis of a unique cyclopentyl head group, known as calditol. Calditol-linked glycerol dibiphytanyl glycerol tetraethers (GDGTs) are membrane-spanning lipids in which calditol is ether-bonded to the glycerol backbone. They are found in a subset of thermoacidophilic archaea of the Sulfolobales order within the Crenarchaeota phylum, but they are also found in other archaeal phyla including the Korarchaeota and Marsarchaeota. These unusual lipids are required for growth in extremely low pH environments.

The available structural data indicate close similarities between the polar lipids found in species of the same genus. Thus, the closer the phylogenetic relationships of the organisms, the more similar the lipid compositions of their membranes. These ether-containing lipid structures are more stable than the ester-containing lipids of bacteria and eukaryotes. This may have resulted in part through evolution, from the extreme environments inhabited by many archaea.

The extreme environments that some archaea thrive in include hot springs and strongly acidic, salty, and/or alkaline lakes. For example, *M. jannaschii* grows optimally at 85°C and pH 6, *Thermoplasma acidophilum* at 55°C and pH 2, and *Halobacterium salinarum* in near-saturated salt brines. Archaea that can not only survive but also grow at temperatures above 100°C are known.

A primary role of any cell CM is to provide a selective barrier between the external environment and the cytoplasm. Given the extreme environmental conditions conducive to archaeal growth, it is not surprising that their membranes contain lipids that differ markedly from those of bacteria and eukaryotes. The presence of ether rather than ester bonds contributes to their chemical stability, particularly at high temperatures and extreme pH values. Surprisingly, the glycerol ethers of archaea contain an *sn*-2,3 stereochemistry that is different from that of the *sn*-1,2 stereochemistry of glycerophospholipids of the other domains of life. The unique basic lipid core structures of these two lipid types are depicted in Fig. 3(b).

Two major classes of archaeal lipids include the archaeol lipids (diphytanyl glycerol diethers) and the caldarchaeol lipids (dibiphytanyl diglycerol tetraethers). The caldarchaeol lipids span the membrane, and liposomes made from these lipids preferentially form monolayers rather than the bilayers formed from conventional glycerophospholipids. Many of the tetraether lipids are phosphoglycolipids containing one or more sugar residues at one pole, most commonly gulose, glucose, mannose, and/or galactose, and a phosphopolyol moiety, such as phosphoglycerol or inositol, on the other. The more bulky sugar residues probably face outward, and the phosphate residue may face toward the cytoplasmic side of the membrane. Depending on the growth temperature, certain thermophilic archaea are capable of controlling membrane fluidity by altering the number of cyclopentane rings (from 0 to 8 in caldarchaeol lipid chains).

Archaeal OMs

Many hyperthermophilic *Crenarchaeota* have two-dimensional crystalline arrays of (glyco-)protein subunits (the S-layer) as the most rigid component of their cell walls. Thus, the typical cell wall of archaea consists of a pseudo-crystalline S-layer. Within the crenarchaea, the S-layer is usually the only cell wall component, but glycosylated S-layers are found in (hyper)thermophilic cren- and euryarchaea as well as halophilic archaea. Moreover, other cell wall structures such as proteoglycan-like S-layers (Halobacteria), glutaminyglycan (Natronococci), methanochondroitin (*Methanosarcina*) and double layered cell walls with pseudomurein (*Methanothermus* and *Methanopyrus*) have also been identified. The euryarchaeal methanogen, *Methanomassiliicoccus luminyensis*, cells of the ARMAN group, and the SM1 euryarchaeon provide further examples of two-layered cell envelopes. Subunits of the S-layer are directly anchored to the CM by stalk-like structures. The space between the CM and the S-layer is called the 'quasi-periplasmic space' by analogy to the equivalent structures in Gram-negative bacterial cell envelopes.

Ignicoccus is a hyperthermophilic archaeon belonging to the *Desulfurococcales* subdivision of the *Crenarchaeota*. It is a chemolithoautotrophic organism that obtains its energy by the reduction of elemental sulfur with molecular hydrogen. Cells of *Ignicoccus* have been examined ultrastructurally following cultivation in cellulose capillaries and processing by high-pressure freezing. They consistently showed a cell envelope structure previously unknown among the archaea: CM and OM separated by a periplasmic space of variable width (20–200 nm) containing membrane-bound vesicles. The outer sheath, approximately 10 nm wide, seemed to resemble the OMs of Gram-negative bacteria. The *Ignicoccus* sheath contains three types of particles: (1) numerous irregularly packed single particles, about 8 nm in diameter; (2) putative pores with a diameter of 24 nm; and (3) tiny particles arranged in a ring with a diameter of 130 nm surrounding the pores. Clusters of up to eight particles, each particle 12 nm in diameter, were conspicuous. Freeze-etched cells exhibited a smooth surface without a regular pattern, with frequent fracture planes through the outer sheath. This observation indicated to the researchers the presence of an OM and the absence of an S-layer. The study illustrated the novel complex architecture of the cell envelope of *Ignicoccus*. Comparative studies suggest that OMs of prokaryotes have evolved independently at least three times, once in Gram-negative bacteria, once in high G+C Gram-positive bacteria, and once in *Crenarchaeota*.

Membrane Transfer Between Cells

Ignicoccus lives in symbiosis with another archaeon, a very small, single-celled organism called *Nanoarchaeum equitans* (see Fig. 4). The *Nanoarchaeum* cell has one of the smallest genomes yet sequenced (less than 500,000 bp). In fact, too few genes are present to

Fig. 4. An electron microscopic depiction of an *Ignicoccus* cell (bottom), showing the inner and outer membranes, in symbiotic association with two *Nanoarchaeum* cells (top).

code for all of the biological functions thought to be essential for life. It can live only together with *Ignicoccus*. Among the missing functions are the enzymes that catalyze lipid biosynthesis. If these enzymes are really absent from this organism, then how does *Nanoarchaeum* get its lipids for construction of its CM?

Ultrastructural analyses reveal not only the two-membrane envelope of *Ignicoccus*, but also the presence of intraperiplasmic vesicles. Because the lipid and protein compositions of the inner and outer membranes are different, it has been possible to establish that these vesicles derive from the inner membrane of *Ignicoccus*. Moreover, the lipids in the nanoarchaeal membrane are very similar, if not identical, to those in the CM of *Ignicoccus*.

These observations led to the postulate that one organism makes the lipids for both. Some of the membrane transport proteins in the nanoarchaeal membrane of one organism may also derive from its symbiotic partner cell. The details of the transfer process still need to be confirmed. However, it already seems likely that these symbiotic archaea have developed mechanisms for intercellular communication and molecular transfer involving periplasmic vesicles that are unique to them. Alternatively, elucidation of such mechanisms may lead to the discovery of analogous processes in bacteria and eukaryotes.

Conclusions

Prokaryotes, including bacteria and the much less well-studied archaea, possess cell envelopes of extremely varied compositions and structures. In both prokaryotic domains of living organisms, as in organelles of eukaryotes, the envelopes can possess one or two membranes. The two membranes always consist of different combinations of lipids and proteins. We are now coming to appreciate the complexities of the assembly machineries that function to construct these envelopes. Many are present in specific membranes while others span the entire cell envelope structures. Moreover, completely different transport apparati are found in the inner and outer membranes of organisms that have both. Evaluation of the structural data available for the OMs of Gram-negative bacteria, high G+C Gram-positive bacteria, and archaea leads to the conclusion that prokaryotic OMs have probably evolved independently in these three organismal types. It is clear that further research will be required to clarify the many important but poorly understood issues dealing with basic aspects of the functions, structures, biogenesis, and evolution of prokaryotic OMs. Moreover, novel processes and mechanisms are likely to come to light. This article thus serves as a progress report of prokaryotic membrane research efforts that will hopefully provide a basis for future advances.

Bacterial and Archaeal Cell Structure

Cell Boundaries of Microorganisms

Most bacteria and archaea constantly face changing and often hostile environments. Therefore, their cell envelopes must provide adequate protection against physical, chemical and biological stresses while allowing an adequate influx of nutrients and efflux of waste products and signaling molecules. As bacterial and archaeal cell envelopes differ fundamentally in their composition and structure, they will be discussed separately.

Bacterial Envelope Structure

Traditionally, bacterial envelopes are classified into one of two groups using the Gram stain. Gram-negative bacteria possess a cytoplasmic membrane (CM), a thin peptidoglycan (PG) layer and an outer membrane (OM), while Gram-positive bacteria lack the OM and produce a thicker PG cell wall (Fig. 1, upper panel). Some notable exceptions of bacteria that lack a continuous PG layer exist, such as in *Mycoplasma*. The CM of bacteria is a phospholipid bilayer, its two leaflets are clearly distinguishable using electron microscopy at high magnification (Fig. 1, lower panel). The CM is water-permeable but impermeable to polar organic solutes and inorganic ions. This allows the cells to generate an inward-directed proton motive force, which is used to facilitate essential processes such as ATP syntheses and motility. Accordingly, a multitude of proteins involved in energy production, transport and secretion are embedded in the CM.

The major stress-bearing component of most bacteria is the PG network that envelopes the cell. PG is composed of long glycan strands of alternating *N*-acetyl glucosamine and *N*-acetyl muramic acid molecules which are crosslinked by short peptide chains. The CM and the PG are separated by a 10–20 nm wide space. In Gram-positive and -negative bacteria, the PG is similar in chemical composition and synthesis, but the PG layer of Gram-positive bacteria is substantially thicker (~40 nm) than in Gram-negatives. Lipoteichoic acids associated with the CM, teichoic acids and polysaccharides, which are linked to the PG, extend through the peptidoglycan network and form a negatively charged, loose outer layer. In Gram-negative bacteria, the PG is a ~4 nm thin single layered mesh. The glycan strands run in a circumferential fashion around the cell body and the peptides roughly parallel to the long axis of the cell (see Fig. 2). While the PG of Gram-positive cells is generally much thicker than that of Gram-negatives, the thickness does not serve as a reliable phylogenetic marker as several species possess intermediate thicknesses, and Gram-negative and -positive staining organisms may be found in the same class. Furthermore, the thick PG layer of *Bacillus subtilis* and *Acetoneema longum* is converted to a thin layer reminiscent of the PG of Gram-negative bacteria during then initial stages of sporulation. The PG layer in Gram-negative bacteria is enclosed by the OM. The OM itself differs chemically from the CM as it is composed of an inner leaflet and an exterior leaflet of lipopolysaccharides (LPS) that provide the cell with a negatively charged barrier. Some Gram-positive and -negative bacteria produce an additional proteinaceous surface layer on top of the PG layer or OM, respectively. This S-layer is mostly composed of one protein that self-assembles into oblique, square, or hexagonal lattice symmetries. Since the S-layer proteins arrange into a two-dimensional crystal *in vitro*, they can readily be studied by electron microscopy (Fig. 3). Finally, the outmost layer of many Gram-positive and -negative bacteria is a thick capsule of vastly variable polysaccharide associated with the OM or PG. This capsule provides additional protection against desiccation and is of clinical relevance as it facilitates cell attachment and evasion of the host immune defense.

Archaeal Envelope Structure

While the chemical composition of CM, PG and OM is conserved among the bacteria, archaea produce a more diverse and species-specific set of envelope components (Fig. 4(a)). The lipids comprising the CM are unique for the archaea. Some species produce diether lipids that arrange into two leaflets whereas others possess tetraether lipids with up to 8 cyclopentane rings, thus forming a monolayer. Archaea also produce a variety of further structural components that envelope the CM. Some Euryarchaeota possess a cell wall composed of sugar polymers. However, unlike the PG of bacteria, archaeal cell walls differ vastly regarding their chemical composition and properties. Methanochondroitin for example is a fibrillar polymer that forms a rather loose matrix around aggregated cells. In contrast, pseudomurein has a thickness of approximately 15–20 nm and resembles PG in general architecture and rigidity. In most archaea that lack polymeric cell walls, an additional proteinaceous layer provides protection and maintains the cell shape. Most commonly, this is an S-layer with similar properties as their bacterial counterparts. However, while bacterial S-layers are only five to 20 nm thick, they may reach a thickness of up to 70 nm in archaea (Fig. 4(b)). Another type of protein layer is the tubular sheath of the filamentous growing *Methanospirillum* and *Methanosaeta* species. This sheath is composed of circumferential rings that envelope the entire filament. The circumferential hoops can clearly be seen using transmission electron microscopy (TEM). Capsule-like structures have been described for several archaea and genomic analysis suggests that many archaea encode genes for capsule systems.

Cell Shape

Bacteria and archaea exhibit a broad diversity of cell shapes and cell sizes (Fig. 5). These features are tightly controlled through elaborate cell division machineries and structural features that maintain their intrinsic morphology. While some archaea share both structural and cell division components with bacteria, others have systems homologous to eukaryotic division machineries.

Fig. 3 (a) Final refined positions of sub-tomograms of S-layer proteins plotted back onto a tomogram of a *C. crescentus* cell stalk with the corresponding refined orientations. Positions have been coloured from blue (high cross-correlation of alignment) to red (low cross-correlation). (b) The same plot as panel A, except each hexamer position is illustrated with the sub-tomogram average (green volumes). One hexamer is highlighted in blue, and the hexamers directly contacting it are shown in orange. (c) A zoomed view of the hexameric lattice revealed by cryo-ET and sub-tomogram averaging. For most bacteria, the PG is both essential and sufficient to regulate and maintain their shape. However, how the PG synthesis is orchestrated to result in a particular shape is not well understood for most morphologies and organisms. In general, it is believed that cytoskeletal elements direct the PG synthesis machinery to the appropriate positions. In *E. coli*, the actin-like cytoskeletal protein MreB coordinates localization of the PG synthesis machinery and, consequently, the insertion of PG precursors. MreB itself preferentially localizes to regions of negative curvature. The insertion of PG at these sites results in the growth of *E. coli* as a straight rod. In some cases, the cytoskeleton may play a more active role in shaping a cell. The vibrioid cell shape of *Caulobacter crescentus* is the result of crescentin,

a homologue to eukaryotic intermediate filaments. This protein coats the inner curvature of the cytoplasmic side of the CM. In contrast to coccoid spheres, alternative cell shapes offer the possibility of subcellular organization. In rod shaped cells for example the cell can distinguish between polar and midcell regions. In some bacteria, structures required for motility and chemosensing are predominantly found at one or both poles of the cell. The differently curved membrane at the pole can establish polarity of bacterial cells, and landmark proteins can recruit further proteins to the pole or protein gradients along the axis of the cell.

The cell shape maintenance in archaea is less well understood. CetZ, a protein related to eukaryotic tubulin and bacterial FtsZ, was shown to be essential for the development of rod-shaped *Haloferax volcanii* cells. This protein forms an additional layer underneath the membrane in cells producing high levels of this protein.

Cell Division

With few exceptions, the cell division machinery is necessary to reliably divide a cell into two daughter cells of similar volume and content. In nearly all bacteria, cell division is orchestrated by the tubulin homologue FtsZ. This specialized cytoskeletal element assembles into circumferentially orientated, overlapping filaments at the cytoplasmic side of the CM, which marks the division site and provides an assembly platform for the cell division machinery (Fig. 6). In Gram-positive bacteria, cell division occurs by septation. Here, the CM is pulled inwards and two new PG layers grow in parallel into the septum. At the outer rim of the septum, a PG bridge connects the old cell wall material of the mother cell both to each other as well as to new PG layers. Once septation is complete, the two daughter cells are fully separated and split from each other. Division of Gram-negative bacteria follows a similar scheme with some variations. The constriction of the Gram-negative cell envelope starts either symmetrically, or asymmetrically at one side of the cell, before occurring circumferentially. Additionally, instead of forming a compact thin septum, the OM and PG lag behind the CM that moves into the center of the cell first, forming a V-shaped constriction. Here, the hydrolysis and synthesis of the PG bridge is speculated to be more controlled as it needs to move inward following the FtsZ ring while preventing premature rupture.

Archaea also divide by binary fission, but exhibit a higher diversity of systems and modes of cell division than bacteria. Most Euryarchaeota, Thaumarchaeota, Nanoarchaeota and Korarchaeota encode an FtsZ-based division machinery, while the Crenarchaeota possess a system homologous to the eukaryotic endosomal sorting complex required for transport III (ESCRT-III). Cell division of these archaea may occur either symmetrically or asymmetrically.

Interaction With the Environment

Bacteria and archaea have developed an extraordinary arsenal of molecular machinery to interact with, as well as influence, the environment around them. The cells are able to sense their surroundings, determine the levels of nutrients, change the environmental milieu, and provide defenses for themselves and their neighbors. The following sections describe how bacteria and archaea interact with their environment, highlighting the roles of motility apparatus, membrane vesicles, secretion systems, pili and, hami.

Motility

Some of the most striking structural features of bacteria and archaea are the proteinaceous ultrastructures required for cellular motility. Several distinct types of motility machineries have evolved in microorganisms, each adapted to a certain life style and environment.

Fig. 6 (a) FtsZ forms bands of filaments completely encircling *C. crescentus* NA1000/CB15N division site with filaments near the inner membrane IM. The Z ring (arrow) is continuous. The cytoplasm (beige), periplasm (blue), and space between the OM and S layer (cyan) have been coloured for clarity. (b) 10-nm thick electron cryotomographic slice of an *E. coli* minicell formed from cells expressing *Thermotoga maritima* FtsZ and FtsA proteins, with a deeply constricted area showing cross-sections of FtsZ and FtsA filaments (black dots marked with white arrows). Distance between FtsZ filaments and IM is around 12 nm (inset in b). (a & b). Modified from Szwedziak, P., Wang, Q., Bharat, T.A.M., Tsim, M., Löwe, J., 2014. Architecture of the ring formed by the tubulin homologue FtsZ in bacterial cell division. *eLife*, 3.

Swimming Motility

Due to their small size, viscous forces are predominantly influencing microorganisms that move through water bodies. Therefore, reciprocal movements do not propel the cell. Bacteria and archaea solve this problem by using long rotating filaments that generate a fluid flow. Surprisingly, the bacterial flagellum and the archaeal archaellum have evolved separately, although they facilitate the same task.

The overall architecture of the flagellum can be divided into three major parts: The long helical filament extending from the cell body, a flexible hook and the envelope embedded basal body which comprises the rotary motor. Although the principal flagellar components are conserved among all flagellated bacteria, further proteins can modify the flagellar motor properties. Several additional periplasmic discs and ring structures are found to provide an increased structural support as well as a scaffold that allows more stators to be included in the motor. This results in increasing widths of the C- and stator ring (Fig. 7(a-i)). Both features allow cells to swim at a higher speed and torque.

Due to a similar assembly mechanism and homology of some components, the archaellum structurally resembles bacterial type IV pili (T4P) rather than the flagellum. Contrary to the flagellar filament, the archaellum is not hollow. Here, the prepilins are assembled into the pilus at the base of the growing archaellum. The motor is a multiprotein complex, however, rotation of the archaellum is powered by ATP hydrolysis and not by an ion-flux. While recent advances have elucidated the structure of the archaellum, several components and functions remain to be defined (Fig. 7(k and l)).

Surface Motility

Besides being required for attachment and biofilm formation, several bacteria possess retractile T4P that can attach to a surface and pull the cell towards the attachment point. This form of motility is referred to as twitching motility. Assembly of the pilus results in its extension, while the disassembly results in its retraction. Both processes depend on ATP hydrolysis. In several organisms, a specialized ATPase facilitates the depolymerization. Non-retractile and retractile T4P are structurally very similar.

An additional surface motility mechanism has been described for *Myxococcus xanthus*. The structural requirements of the so-called gliding motility, known as adventurous or A-motility, are not entirely understood. The current model of this mode of motility is based on the consecutive adhesion of OM lipoproteins to a surface, followed by the movement of the cell relative to

that adhesion point, and the final release and disassembly of the lipoprotein complex at the lagging end of the cell. The involved protein complex appears to span the entire cell envelope. The release of a slime further facilitates the movement across the substratum.

Chemotaxis

In order to optimally benefit from the ability to move through the environment, many bacteria and archaea can sense their chemical environment and control their motility accordingly. This allows the cells to seek out their preferred environment and evade potentially harmful conditions.

Chemotaxis is best understood in the model organism *Escherichia coli*. Here, the cells can sense environmental cues such as sugars, amino acids or toxins via chemoreceptors that are anchored in the CM. The receptors, or MCPs (for Methyl accepting chemotaxis proteins), form trimer-of-receptor dimers, and these trimers are in turn arranged in highly ordered arrays, where six trimers form the corners of a hexagon (Fig. 8). This receptor packing, and thus the distance between the centers of the hexagons of 12 nm in the lattice, is highly conserved and universal across the bacteria and archaea.

In *E. coli*, the cytoplasmic tips of the receptors are networked by rings formed by the histidine kinase CheA and the linking protein CheW. CheA autophosphorylates and transfers this phosphoryl group to a messenger protein CheY upon an increase of repellents or a removal of attractants. The phosphorylated messenger protein CheY binds to the flagellar motors and biases the direction of flagellar rotation from the default counter clockwise (CCW) to clockwise (CW). This results in a tumbling behavior where the cells randomly reorient their cell axis. Once all flagella of the cell return to CCW, the cells swim smoothly forward (run) in a new direction. The control of frequency and duration of these tumbles result in a biased random walk, which ultimately provides the means to find their preferred environment.

While *E. coli* only possesses one chemotaxis system, more than half of all chemotactic bacteria have additional chemotaxis systems encoded in their genome. Some of these systems lack the transmembrane and periplasmic regions of the receptors, and thus form purely cytoplasmic chemoreceptor arrays. Structurally, these arrays consist of two layers, where each layer is hexagonally packed like their membrane-bound counterparts. The receptors of both layers overlap and are sandwiched in

Fig. 8 Visualization of the highly structured chemotaxis array by cryogenic electron microscopy (cryo-EM) in *Salmonella enterica* mini cells. (a) Viewed from the top, the chemotaxis array assumes a lattice formation (top) that is universal among bacteria (bottom). (b) Illustration of the chemotaxis array highlighting key proteins and their interacting partners that maintain the array: CheA (A, orange), methyl-accepting chemotaxis protein trimers (blue) and CheW (W, yellow). Scale bar in A (top) is 100 nm. Outer membrane (OM), inner membrane (IM). Modified from Briegel, A., Jensen, G., 2017. Progress and potential of electron cryotomography as illustrated by its application to bacterial chemoreceptor arrays. Annual Reviews of Biophysics 46, 1–21. <https://doi.org/10.1146/annurev-biophys-070816-033555>.

between two layers composed of CheA and CheW. While we are beginning to understand the architecture of such cytoplasmic arrays, their function remains largely unclear.

Membrane Vesicles

Membrane vesicles are an essential component found in both Gram-positive and Gram-negative bacteria, as well as in archaea (also referred to as outer membrane vesicles in Gram-negative bacteria). These vesicles are typically spherical, ranging in size from 20 to 100 nm in Gram-positive bacteria and archaea to 100–300 nm in Gram-negative bacteria (Fig. 9). The lipid bilayer composition of the vesicles resembles that of the membrane where the vesicle originated. They can contain cell-wall material, as well as a variable content enclosed by the membrane. In addition, the content of membrane vesicles can be enriched with a diverse set of molecules including LPS, peptidoglycan, nucleic acids, metabolites, and signaling molecules. The mechanism by which membrane vesicles are generated is still under investigation.

Membrane vesicles have many proposed functions: bacterial communication, modulation of stressful environments, components for biofilm formation, and defense strategies. The membrane vesicles can be filled with specialized cargo that elicit specific types of response, including the recognition of self and non-self organisms. For the acquisition of nutrients, outer membrane vesicles (OMVs) can be filled with proteases and glycosidases, or with DNA and proteins that can be a source of food for the community. Recent studies have also demonstrated that interactions with specific hosts can bias the proteins found in membrane vesicles to those that are important to the bacteria-host relationship, including adhesions for binding to specific cell types. For instance, the Gram-positive bacteria *Staphylococcus aureus* produce membrane vesicles that contain beta lactamase as a way to protect the local environment from the antibiotic penicillin. In addition, membrane vesicles have also been shown to provide a defense against bacteriophage infection by acting as a decoy. Thus, membrane vesicles play an essential role in the bacterial and archaeal life cycle by modulating the environment in favor of their survival.

Secretion Systems

In addition to releasing membrane vesicles into the environment, bacteria and archaea have developed various mechanisms to transport unfolded or folded proteins across their membrane(s) and into the local environment or across the membrane of a target cell. Some systems allow a protein to move from the cytoplasm directly to the extracellular space in a one-step process. Others require several steps for the target protein to exit the cell via a transport system through the CM, followed by a second transport system that spans the OM and/or cell wall. Upon translocation, the proteins remain either attached to the cell envelope, are released into the extracellular space, or are transferred directly into the target cell. Thus far, as many as sixteen unique complexes have been shown to be involved in protein transport across the membrane. Each system plays a specific role in bacterial and archaeal physiological processes. Furthermore, these systems are the primary method for the release of bacterial effector proteins that act on other cells in the environment. Some secretion systems are universal among bacteria and archaea, such as the Sec and Tat pathways, while others are restricted to a specific phylum or species. The same is true for the cargo of each system, some transporting a wide range of proteins and others are specific to just a small number of proteins. The secreted proteins have many roles in the bacterial and archaeal life cycle, including uptake of nutrients, expression of virulence factors, and attachment to target cells. Gram-negative bacteria have multiple secretion systems: Sec, Tat, type 1 secretion (T1SS), T2SS, T3SS, T4SS, T5SS, T6SS, and T9SS. Gram-positive bacteria have at least four systems, Sec, Sec2A, Tat, and T7SS, and only Sec and Tat have been identified in archaea so far.

Fig. 9 Cryo-EM of membrane vesicles isolated from *Streptomyces*, demonstrating the variety of sizes and variability in contents. Three types of vesicles are noted: Empty (a), partially filled, with or without external membrane complexes (b), or heavily filled with material (c). Scale bar 200 nm. Modified from Schrempf, H., Koebisch, I., Walter, S., Engelhardt, H., Meschke, H., 2011. Extracellular *Streptomyces* vesicles: Amphorae for survival and defense. *Microbial Biotechnology* 4 (2), 286–299.

Because of the large number of secretion systems across bacteria and archaea, this section will highlight only those systems with significant ultrastructural information.

Type II Secretion System

The type II secretion system (T2SS) is only found in Gram-negative bacteria where it is responsible for secreting folded proteins from the periplasm through the OM. Proteins that are destined for the T2SS are first transported in an unfolded state across the CM by the Sec or Tat systems. Once in the periplasm, the protein is folded and then transported into the extracellular space by the T2SS. This secretion system is an important component in pathogenesis, and many pathogens utilize this pathway to deliver toxins to target cells. A well-studied example of this mechanism is the transport of the cholera toxin during *Vibrio cholerae* infection. The T2SS is thought to work by a piston mechanism, where the cholera toxin is mounted to a platform on the periplasmic side of the CM and then pushed through the OM pore. This export is powered by the retraction of the pseudopilins (Fig. 10).

Type III Secretion System

The type III secretion system (T3SS) is also known as the injectisome because its structure resembles a needle and syringe and acts in a similar fashion. This system is found exclusively in Gram-negative bacteria, where it spans the whole cell envelope, as well as the membrane of its target cell. This provides the opportunity for the transport of unfolded proteins directly into the target cell. This transfer of bacterial effectors typically facilitates the creation of a more favorable environment for the delivering bacteria. Three main components of the T3SS have been characterized: the basal body, the needle and the translocon. The needle extends from the base into the extracellular space and consists of a hollow channel that permits transport of unfolded proteins. The translocon is responsible for the transport of effector proteins upon contact with the target cell. The T3SS has been structurally well characterized, and recent studies provided detailed insight into the structural variations of the T3SS in *Chlamydia* and *Salmonella* (Fig. 11).

Type IV Secretion System

The function of the type IV secretion (T4SS) system is used for bacterial conjugation, where it enables the cells to secrete a wide variety of molecules including single stranded (ss) DNA and ssDNA-protein complexes directly into a target cell. There are two types of T4SS: the retractable T4aSS and the non-retractable T4bSS. The T4SS spans the CM and OM of Gram-negative bacteria as well as the membrane of the target cell. The secretion system provides the means to export and import DNA, and thus contributes to spread of antibiotic resistance genes. The structure of the T4SS is similar across all identified T4SS variants, though the role of an extracellular pilus in some systems is still unknown. This system is important for virulence in many bacteria, such as in the pathogen *Legionella pneumophila*, where the structure of this T4bSS has been recently solved (Fig. 12). In this organism, the T4bSS transports effectors into the target cells in order to disrupt the host's defense, and thus enabling bacterial colonization.

Type VI Secretion System

Similar to the T3SS, the type VI secretion system (T6SS) transports proteins from the bacterial cytoplasm directly into the target cell. Found only in Gram-negative bacteria, this system is thought to be both a form of communication and competition

Fig. 10 Schematic representation of the secretion of *Vibrio cholerae*'s cholera toxin by a piston-driven mechanism of the T2SS. Cholera toxin (gold) is loaded on the pseudopilus tip (grey). The toxin is then pushed into the periplasmic portion of the membrane channel by the extension of the pseudopilus. Secretion of the toxin is permitted by the opening of the membrane channel and continued growth of the pseudopilus. Modified from Reichow, S.L., Korotkov, K.V., Hol, W.G.J., Gonin, T., 2010. Structure of the cholera toxin secretion channel in its closed state. *Nature Structural and Molecular Biology* 17 (10), 1226–1232. doi:10.1038/nsmb.1910.

In situ structure of the *Legionella* Dot/Icm type IV secretion system by electron cryotomography. *EMBO Reports* 18 (5), 726–732. <https://doi.org/10.15252/embr.201643598>.

among various bacteria. The T6SS secretes bacterial toxins either into other bacterial cells in the local environment, or into eukaryotic cells. The T6SS is highly efficient in protein transport, and it provides the cells with both defensive and offensive protection against other bacteria that also employ the T6SS. In addition, this system has been implicated in bacterial response to stress and for self-recognition. Furthermore, it contributes to horizontal gene transfer, since it uses this system to kill opponent cells. The resulting lysis frees the DNA that can subsequently be taken up by other secretion systems.

The T6SS is homologous to the tail structure found in bacteriophages. Structurally, the base of the T6SS is anchored to the CM, and upon contraction of a sheath-like structure, the inner tube is propelled into a target cell, puncturing the target cell's membrane with a spike-like protein tip. A well-studied structural model for the T6SS comes from *M. xanthus*. In this organism, the T6SS is characteristic tube-shaped structure within the cell (Fig. 13(a)). The tube structure is extended into the cytoplasm and anchored to the CM. Upon external trigger the sheath of the tube constricts propelling bacterial effectors into the target cell. In the bacterium *Pseudoalteromonas luteoviolacea*, a structure termed the MAC complex induces metamorphosis in tube worms. Here, the T6SS form a large array of tubes held together by a protein mesh, that are released into the environment and act as 'land mines' that induce the metamorphosis of the tube worm.

External Appendages

Pili (Also Known as Fimbriae)

Bacteria and archaea have evolved a number of external appendages that can be used for attachment, secretion, electron uptake, and motility. Such structures include four types of pili. Gram-positive and Gram-negative bacteria have similar types of pili, however their fine structures differ. The chaperone-usher pili are mainly found in Gram-negative bacteria and are used for host attachment and virulence. Chaperone-usher pili are typically 1–2 μm in length with the pilin subunits arranged in a helical pattern. This pilus architecture provides the ability to stretch.

In addition to the functions mentioned for the chaperone-usher pilus, the type 4 pilus (T4P) is also involved in twitching and gliding motility. T4P can be several microns in length with a diameter of 6–9 nm. T4P are unique among the pili because some variants have the ability to extend and retract, which provides the means for the cell's motility. During assembly, pilins are removed from the CM and assembled in the periplasmic space by the T4P basal body, causing the filament to extend out into the extracellular space. There are two types of T4P, Type IVa (T4aP) and Type IVb (T4bP). T4aP has a range of functions including cell motility and DNA transfer, while T4bP is specifically used for host colonization. The Gram-negative organism *V. cholerae* has a unique, well-studied form of the T4bP called the toxin co-regulated pili (TCP). The TCP is essential to the *V. cholerae* infection cycle, providing a means of attachment for the bacterium when it enters the mucosal regions of its host. Additionally, it enables the cells to form microcolonies. The different T4P types are remarkably similar in composition and structure, though only T4aP have the ability to retract (Fig. 14). TcpA is the major pilin subunit for both systems, which forms the extracellular appendage.

The conjugative T4P pilus, also called F-pilus or F-like pilus, is the primary method used between bacteria for the transfer of genetic information. This structure is present only in Gram-negative bacteria and requires a specific plasmid that codes for the essential components of this conjugative pilus. This system is unique as it requires the use of a T4SS for assembly. The current model of this system is that once two cells are connected, the pilus is retracted in order to bring the two cells together, thus allowing for the transfer of genetic material.

Lastly, the type 5 pili (T5P) are unique to the *Bacteroides* phylum, consisting of two types of pilin appendages: a long pilus that extends approximately 0.3–1.5 μm from the cell body, whereas the short pilus is restricted to 80–120 nm. This pilus type has several roles including adhesion, aggregation, biofilm formation, and virulence.

Fig. 13 Visualization of the T6SS in vivo by cryo-EM. The T6SS in the extended (a) and contracted state (b) in *Myxococcus xanthus*. The extended version spans a significant portion of the cell and once triggered contraction delivers effectors to the target cell. Scale bars: 50 nm. Modified from Chang, Y., Rettberg, L.A., Ortega, D.R., Jensen, G.J., 2017. In vivo structures of an intact type VI secretion system revealed by electron cryotomography. *EMBO Reports* 18 (7), 1090–1099. <https://doi.org/10.15252/embr.201744072>.

Fig. 14 T4P. *Vibrio cholerae* exhibits a unique type IV pilus apparatus called the toxin-co-regulated pilus machine (TCPM). A. Using cryo-EM, the pilated TCPM (white arrow) and non-piliated basal body (black arrow) are identifiable on the cell surface. Image processing enables the user to gain greater detail of the TCPM allowing the comparison of the pilated (b) and non-piliated states (c). Scale bars: 50 nm (A), 10 nm (B, C). Modified from Chang, Y., Kjaer, A., Ortega, D., et al., 2017. Architecture of the *Vibrio cholerae* toxin co-regulated pilus machine revealed by electron cryotomography. *Nature Microbiology* 2, 16269. <https://doi.org/10.1038/nmicrobiol.2016.269>.

Fig. 15 The archaeal hami of *Candidatus Altiarchaeum hamiconxum* visualized by negative stain EM (a, b) and cryo-electron tomography (c) demonstrating the characteristic barbed structure filament with tripartite tips. Scale bar: 500 nm. Reproduced from Perras, A.K., Daum, B., Ziegler, C., et al., 2015. S-layers at second glance? Altiarchaeal grappling hooks (hami) resemble archaeal S-layer proteins in structure and sequence. *Frontiers in Microbiology* 6, 543.

Other Cell Attachment Structures

Hami

Some archaea, such as the *Candidatus* Altarchaeum *hamiconexum*, have an additional, unique appendage that is used for attachment to surfaces, other cells, as well as important in biofilm formation in extreme environments. Upwards of a hundred of these pilus-like structures extend from the cell surface, with each hamus having a diameter of 6–8 nm and protruding several microns into the environment. The hami are made of three intertwined filaments. The hamus terminates in a characteristic tripartite structure that resembles a grappling hook (Fig. 15). Many hami have three barbs emerging approximately 47 nm apart along the main thread. The assembly of this structure is thought to be mediated by the Sec pathway, moving the three subfilaments into the periplasm for hamus assembly. However, the filaments are not related to known bacterial filaments and recent research suggests that it may have evolved from modified S-layer proteins.

Bacterial Bioluminescence

Introduction

The remarkable phenomenon of bioluminescence no doubt intrigued the first humans, and it still fascinates today. By the dawn of recorded history, the ability of certain living things to make light had been observed and pondered by different cultures. It would have been obvious that many different organisms produced light, including fireflies, glowing mushrooms, and a variety of marine animals. However, microbial bioluminescence must have posed a particular puzzle, as the producers themselves were too small to be seen as individuals and awaited discovery in later centuries. Nonetheless, the glow of bacteria from a dead caterpillar or from a rotting fish would have been familiar well before the microbial nature of the phenomenon was understood.

The advances in our understanding of bacterial bioluminescence in many ways parallel the progress in the field of microbiology itself. In the 1600s, microorganisms or “animalcules” were discovered and observed microscopically, and by the 1700s it was proposed that some microbes produced bioluminescence. In the 1800s, breakthroughs in the ability to grow and isolate bacteria as purified clonal colonies allowed scientists to connect certain properties with specific bacteria. In this way, several species of bioluminescent bacteria were isolated, characterized, and catalogued. In the late 1800s and early 20th century, as the germ theory of disease was being developed, so too was it suggested that the light from some bioluminescent animals might actually be produced by symbiotic microbes, a notion that was confirmed in the early 20th century. The mid twentieth century saw great advances in our biochemical understanding of bacterial physiology, and the biochemistry of bacterial bioluminescence was likewise elucidated. As the field of bacterial genetics grew and its tools became more sophisticated in the late twentieth century, so too were the bacterial genes responsible for bioluminescence characterized first by mutational analysis and later as an early example of successful cloning.

Bioluminescent bacteria were also at the forefront of the field of “sociomicrobiology”, a term coined in 2005 to connote that some microorganisms exhibit group behaviors; emergent properties that are absent in isolated individuals. This concept of sociomicrobiology very much has its roots in observations made decades earlier that most bioluminescent bacteria use pheromone signaling to coordinate their decision to turn on their luminescence.

Standing on the shoulders of this long research history, modern scientists continue to add new discoveries. This article summarizes discoveries both old and new relating to bacterial bioluminescence, and highlights some mysteries that remain.

Bacteria That Produce Light

To date, the naturally bioluminescent bacteria described have belonged to three families, all within the gamma-proteobacteria class of Bacteria; the Vibrionaceae, the Shewanellaceae, and the Enterobacteriaceae. Bioluminescent bacteria are often found in mixed microbial communities, and the experimental introduction of a single gene cluster, the *lux* genes (discussed below), can confer bioluminescence on a wide range of bacteria, so it is noteworthy that relatively few bacteria have acquired and retained this trait. By contrast, many useful innovations found on similarly compact genetic loci have been shared broadly across the Bacteria domain, suggesting that perhaps the relative fitness costs and benefits of bioluminescence have constrained the range of bacteria for which it has a net positive value. This section will list and briefly describe the known bioluminescent bacteria, while their habits and ecology will be discussed further in a later section.

Bacterial bioluminescence is most often seen in members of the Vibrionaceae, which encompasses a number of marine and estuarine species. Bioluminescent bacteria are frequently found in coastal seawater, but they can also be isolated from deeper water, as well as from animal gut tracts, light-emitting organs, and surfaces. Such isolates are almost invariably representatives of the Vibrionaceae, and can be classified into the genera *Vibrio* and *Photobacterium*. It has been suggested that a clade representing a phylogenetic intermediate between *Vibrio* and *Photobacterium* warrants a separate genus, named *Aliivibrio*, but this nomenclature has not been adopted universally. Best known among this clade of bioluminescent bacteria is *Vibrio fischeri*, which taxonomists had suggested moving from *V. fischeri* to *Photobacterium fischeri*, and then back to *V. fischeri*, prior to the proposed *Aliivibrio fischeri* nomenclature. For the purpose of this article, the designation *V. fischeri* will be used when referring to this popular model bioluminescent bacterium.

Current knowledge is consistent with the hypothesis that an ancestral member of the Vibrionaceae was bioluminescent and that the *lux* genes underlying this trait were passed down through this lineage, with some branches losing the genes and occasionally re-acquiring them horizontally. Today, only a relatively small fraction of species and strains in this family are luminous. In most of the rare instances of horizontal gene transfer, the *lux* genes have been kept within the Vibrionaceae, but as noted above two other bacterial families include bioluminescent members. Additional bioluminescent bacterial species that have been isolated from seawater are members of the Shewanellaceae family; *Shewanella hanedai* and *Shewanella woodyi*. The former was also isolated from marine sediment and the latter isolated at least once from a squid ink sac.

It appears that at some point the *lux* genes made the leap from the ocean to the land, and into the Enterobacteriaceae family where they now reside in the genus *Photobacterium*, which remains the only known genus of terrestrial bioluminescent bacteria. Indeed, with the exception of rare bioluminescent isolates of *Vibrio cholerae* from freshwater environments, the *Photobacterium* species are unique as non-marine bioluminescent bacteria. Although the taxonomy of these bacteria is somewhat unsettled, at least three bioluminescent species have been described: *Photobacterium luminescens*, *Photobacterium temperate*, and *Photobacterium symbiotica*. These bacteria are symbionts of insect-killing nematodes, and are responsible for the phenomenon of glowing dead insects. At least *P. symbiotica* also appears to be an opportunistic pathogen responsible for glowing wounds.

Although much effort has been devoted to sampling and searching for bioluminescent bacteria, it is possible that other species with the capacity to produce light exist in nature and await discovery. Given the vast scale of the marine environment and its various microhabitats, including potential host species, perhaps sampling has been insufficient and the isolation techniques used in the past will reveal additional bioluminescent bacteria in the future. On the other hand, some host-dependent bioluminescent bacteria have resisted culturing, while other bioluminescent bacteria do not produce bioluminescence when they are cultured and thus may escape notice. Skirting the need for culturing, metagenomic studies that analyze the sequences of DNA isolated directly have reported *lux* gene sequences, suggesting they came from bacteria with the ability to produce light. As these culture-independent data sets expand it will be interesting to investigate more thoroughly the origins of these sequences and their genetic contexts, as this information may reveal previously unknown bioluminescent bacteria.

It is easy to find bacterial species and genera not mentioned in this article that are described or listed elsewhere as bioluminescent, but in many cases these references simply reflect taxonomic name changes. As noted above, *V. fischeri* has been given different genus designations, and confusion can result from several other name changes as well. For example, *S. hanedai* was formerly *Alteromonas hanedai*, *Photobacterium luminescens* has been called *Xenobacterium luminescens*, some *Photobacterium* isolates have been alternately considered subspecies or distinct species, several bioluminescent *Vibrio* species were put in the proposed genus *Beneckea* until that fell out of usage, etc. While experimentalists and taxonomists debate the relative merits of name changes, students of any particular bioluminescent bacterium would be well advised to know the history of its nomenclature or risk overlooking many good studies in the literature that were published during different taxonomic regimes.

Biochemistry of Bacterial Bioluminescence

The core proteins responsible for bacterial bioluminescence are well conserved among the bacteria that produce light. Throughout the biological world, the enzymes generating bioluminescence typically are called luciferases, and bacterial luciferase is a heterodimer of the two proteins LuxA and LuxB, which are sometimes referred to as alpha and beta luciferase subunits, respectively. The LuxAB luciferase sequentially binds reduced flavin mononucleotide (FMNH₂), O₂, and an aliphatic aldehyde (RCHO), and these substrates are converted to FMN, water, and the corresponding aliphatic acid (RCOOH) with the concomitant production of bluish light at around 490 nm wavelength (Fig. 1). Thus, luciferase catalyzes the reduction of oxygen while both the FMNH₂ and the aldehyde substrate are oxidized. The quantum yield of bioluminescence from the turnover of this reaction has been estimated at 0.1–1 photons. Luciferase is an unusually slow enzyme that forms a relatively stable complex with its bound substrates before catalyzing the light-generating reaction. Interestingly, bacterial luciferases seem to fall into two groups that have distinctively “fast” or “slow” luciferase reaction kinetics, although the significance of this observation is unclear.

Besides catalyzing the production of bioluminescence, in the absence of its aldehyde substrate, bacterial luciferase can generate reactive hydrogen peroxide (H₂O₂) through what is called the “dark reaction”. Light itself seems to be the important

Fig. 1 The biochemistry of bacterial bioluminescence. Bold font indicates proteins. Dotted lines indicated protein–protein interactions between LuxAB and YFP or LumP that alter luciferase kinetics and the wavelength of emitted light. See Text for details.

product of Lux system at least in most circumstances, and the “dark reaction” may be simply an unintended side reaction akin to the production of H_2O_2 by aerobic respiratory chains. However, some bacteria, including *Vibrio salmonicida*, are naturally aldehyde-limited with respect to bioluminescence, and it may be the case that Lux-derived H_2O_2 is an important, if often forgotten, product of this system.

Additional core Lux proteins, LuxC, LuxD, and LuxE, act as a complex to (re)generate the aldehyde substrate for luciferase (Fig. 1). LuxD is a thioesterase responsible for redirecting fatty acid metabolism toward generation of the luciferase substrate. LuxD can release a fatty acid from either an acyl-carrier protein (ACP) or from acyl-coenzyme A. The liberated fatty acid is subsequently acted on by LuxE and then LuxC. LuxE, which is referred to as the synthetase, binds the fatty acid substrate and activates the reaction with ATP hydrolysis, while LuxC is the reductase responsible for using NADPH to reduce RCOOH to RCHO. Multiple lines of evidence point to RCOOH and RCHO being the fourteen-carbon molecules myristic acid and tetradecanal, respectively; however, the system is not particularly specific with respect to acyl chain length, and aldehydes longer than six to eight carbons generally will serve as substrates for luciferase. It seems likely that tetradecanal is a primary substrate for luciferase *in vivo*, at least in the bacteria that have been examined in detail, but it remains possible that other aldehydes contribute to bioluminescence.

Some, but not all, light-producing bacteria have additional Lux proteins that contribute to bioluminescence. One of these is LuxG, which shuttles reducing power from NADH to FMN to (re)generate the FMNH₂ substrate for luciferase. Other flavin reductases can substitute for LuxG, which explains why not all bioluminescent bacteria have *luxG*. The role of another auxiliary Lux protein, LuxF, only became clear relatively recently. LuxF protects luciferase by binding to myristylated FMN (myrFMN), which is a byproduct of the bioluminescence reaction that can inhibit LuxAB. LuxF has higher affinity for myrFMN than does LuxAB, so the presence of LuxF will effectively titrate myrFMN before it reaches concentrations that would inhibit LuxAB.

Two additional proteins have been described that interact with luciferase and shift the wavelength of emitted light longer or shorter than the typical 490 nm. The *lumP* gene in *Photobacterium leiognathi* encodes lumazine protein (LumP), which has the unusual effect of shifting the emitted light to a shorter wavelength (~475 nm) bluer light. The opposite effect is seen with the *luxY* gene from *Vibrio* strain Y1, which encodes a yellow fluorescent protein (YFP) that shifts the bioluminescence emitted to a longer wavelength (~545 nm) yellowish light. Strain Y1 is referenced in most reports as *V. fischeri*, but both phenotypic and multi-locus sequencing analyses suggest that this is actually a distinct species, *Vibrio* (or *Aliivibrio*) *sifiae*. Both LumP and YFP interact directly with LuxAB, and these complexes alter both the kinetic and the spectral properties of luciferase. Each of these proteins contains a ligand derived from the riboflavin biosynthetic pathway, 6,7-dimethyl- 8-(1'-D-ribityl) lumazine for LumP and FMN in the case of YFP. Other wavelength-shifting proteins that are not as well characterized as LumP or YFP probably exist, and a preliminary report suggests one such example is responsible for the bluish hue (~472 nm) emitted by *Vibrio azureus*.

Genetics of Bacterial Bioluminescence

The genes encoding the core enzymes responsible for bioluminescence usually are found clustered together in the conserved order of *luxC*, *luxD*, *luxA*, *luxB*, *luxE*, and *luxG*, with a few additions and minor variations (Fig. 2). These genes are typically expressed on a single transcript, often referred to as the *luxCDABEG* operon. Exceptions to this operon organization include the observations that *luxG* is absent in *P. luminescens*, and that in some *Photobacterium* strains *luxF* is found in between *luxB* and *luxE* (Fig. 2). In addition, at the distal end of the operon, downstream of *luxG* but presumably transcribed with *luxCDABEG*, some strains carry *ribB* (also called *luxH*), or a *ribEBHA* cluster (Fig. 2). These *rib* genes appear to encode enzymes related to riboflavin biosynthesis. FMN and lumazine, whose roles in luminescence are described above, are generated as offshoots of riboflavin metabolism, and the role of the *lux*-associated *rib* genes may be to augment levels of one or both of these.

In some bacteria, genes that are co-transcribed with, or adjacent to, the *luxCDABEG* operon are involved in its regulation or function. In *V. fischeri*, the regulatory combination of LuxI and LuxR are encoded with *luxI* at the beginning of the main *lux* operon and *luxR* adjacent and divergent from it (Fig. 2). In some *Photobacterium* strains, *lumP*, which encodes the lumazine protein described above, is found adjacent to the *lux* operon along with *lumQ*, which appears to encode a companion regulator. It is possible that other bacteria cluster luminescence-related non-*lux* genes near the *lux* locus as well, a possibility that will be tested as the genome sequences of more bioluminescent bacteria become available.

The specific sequences of the *lux* genes in different bacteria have provided interesting evolutionary insights. In particular, relatedness between *lux* operons in distinct bacteria has implicated the sources in instances of horizontal gene transfer of this locus. As just one example, an unusual bioluminescent strain of the human pathogen *Vibrio vulnificus* has been isolated, and the sequence of its *lux* operon suggests it was acquired from *Vibrio harveyi* or a related species. Intraspecies *lux*-sequence comparisons have provided additional if more mysterious evidence of selective pressures on luminescence. For example, in two isolates of *V. fischeri*, one noticeably brighter than the other, the *luxCDABEG* genes and the proteins they encode have diverged significantly more than the surrounding housekeeping genes, suggesting relatively recent selective pressure and rapid evolution of Lux even in strains of the same species. In another interesting discovery, some *Photobacterium* strains are merodiploid with respect to *lux*, carrying two similar but genetically distinct copies of this locus, possibly reflecting two subtly different functional roles. Finally, non- or partially functional *lux* loci have been documented in *Vibrio* strains. Thus, the sequences of the *lux* loci have provided insight into their acquisition by some strains, their degradation and loss in others, and what appears to be their relatively recent functional honing.

Fig. 2 Genetic organization of the *lux* locus in different bioluminescent bacteria. The core *lux* genes, *luxC*, *luxD*, *luxA*, *luxB*, *luxD* and *luxE* are found in that in each of the bioluminescent bacteria, while the auxiliary *lux* genes are found in only some.

Regulation of the *lux* Genes

The regulation of the *lux* genes, in other words the conditions under which they are transcribed and translated to produce bioluminescence, has been the focus of considerable research. Although the benefits of bioluminescence and its ecological role(s) for bacteria are covered in a separate section below, this section on the regulation of bioluminescence is intertwined with the discussion of bioluminescence's functional role for the simple reason that one expects bioluminescence to be turned on when it is beneficial for the bacteria and turned off when it is disadvantageous. There may not be a regulatory mechanism common to all bioluminescent bacteria, but there are intriguing common themes.

One clear theme is that many bioluminescent bacteria produce light only when they are in a relatively dense population. As noted above this discovery led to the concept of "sociomicrobiology", which acknowledges that certain emergent properties of bacteria are seen in groups but not in lone cells far from others of their kind. In the case of bioluminescence (and many other bacterial group behaviors), pheromones called "autoinducers" released by the cells must reach a critical concentration to activate gene expression. This phenomenon has been termed "quorum sensing" to connote that a behavior is induced upon cultures reaching some minimum critical population density. A more accurate term might be "quorum-dependent regulation", because in some instances a quorum is necessary but not sufficient. Moreover, a number of complexities in the pheromone-signaling circuitry make it doubtful that the sole purpose of these systems is to census local population density. Many bacteria have multiple pheromones, their synthesis and their receptors are regulated in response to the environment, and in most cases pheromone synthesis is subject to positive-feedback regulation. These elements could allow pheromones to transmit information about the environment across populations. At the same time there must be a population present with which to communicate, and the requirement of a minimum cell density to induce bioluminescence has been widely interpreted from the viewpoint that bioluminescence is meant to be seen, and so it is a waste of resources for a single cell, which does not produce enough light to be visualized.

Quorum-dependent pheromone-mediated control of bioluminescence was first described in *V. fischeri*, which led to the discovery of the LuxR/LuxI signaling system. In *V. fischeri*, LuxI synthesizes the acyl-homoserine lactone (acyl-HSL) pheromone *N*-3-oxohexanoyl homoserine lactone (3OC6-HSL), which can diffuse through cell membranes and thereby becomes a shared extracellular signal. Upon reaching a critical threshold concentration, 3OC6-HSL binds LuxR, which can then activate gene expression. In *V. fischeri*, *luxI* is cotranscribed with the *luxCDABEG* operon, and *luxR* is adjacent and divergently transcribed (Fig. 2). Among other targets, 3OC6-HSL-LuxR activates transcription of *luxI**CDABEG*, which results in both induction of bioluminescence and, in a positive feedback loop, more LuxI and 3OC6-HSL. These functions of LuxI and LuxR are an archetype for similar systems with a diverse array of HSL signals in a wide range of Proteobacteria.

Although LuxR and LuxI are synonymous with the cell-density dependent regulation discovered in bioluminescent bacteria, another form of pheromone signaling is more common in the Vibrionaceae. In most vibrios, a core pheromone-receiving circuit transduces signal perception through a phosphorylation cascade and eventually activates a “master regulator” that controls many genes, including the *lux* operon in most bioluminescent vibrios. *V. fischeri* has this conserved core system in addition to LuxR and LuxI, and its master regulator is named LitR. Unlike similar vibrio master regulators, LitR does not regulate the genes for bioluminescence directly, but instead LitR activates transcription of *luxR*. Homologs of LitR are found throughout the Vibrionaceae, the best known of which are HapR in *V. cholerae* and LuxR in *V. harveyi*, which despite its name is structurally unrelated to LuxR in *V. fischeri*. Interestingly, both *V. fischeri* and *V. harveyi* use AHL signals to control their core pheromone-signaling circuit, but these signals are produced by proteins that are very different from LuxI and apparently arose through convergent evolution. The presence of other non-AHL signals, including a widespread “autoinducer-2” or AI-2 signal, also affects this core signaling circuit and can likewise control bioluminescence. The complexity of this signaling is interesting in its own right and is covered in some of the suggested further reading below.

Some strains do not appear to control bioluminescence with pheromone-mediated signaling, although arguably such exceptions are most notable for their rarity. One such bacterium is *Photobacterium leiognathi* KNH6, which displays dazzlingly bright bioluminescence but does not appear to control bioluminescence based on cell density or pheromone signaling. This observation is more remarkable given that the KNH6 genome encodes the core pheromone-signaling circuitry common to most of the Vibrionaceae, so the regulatory capacity is present but the *lux* genes are not controlled in this common way. Whether this difference in regulation reflects a different use of bioluminescence is unknown.

The regulation of bioluminescence in response to environmental conditions can vary between species, but again *V. fischeri* has emerged as an experimental model, and at least some of the findings in *V. fischeri* reflect observations in other bacteria as well. *V. fischeri* and many other bioluminescent bacteria are found interacting with hosts, either in gut-tract consortia or dedicated symbiotic tissues, and some regulation of *lux* can be interpreted as turning on bioluminescence in a host-like environment. For example, in *V. fischeri* the *lux* operon is controlled by the regulators Fur and CRP such that bioluminescence is induced when access to iron is restricted and complex carbon sources other than glucose support growth, presumably reflecting conditions common in animal tissues.

The *lux* system is also regulated in response to redox conditions, which is germane to discussion below of its possible costs and benefits for the bacteria. Although one report indicates that bioluminescence in *V. fischeri* is maximally expressed under microaerobic conditions, other studies have suggested it is most induced under more oxidative conditions. More than one control mechanism has been implicated in this regard, but especially noteworthy is the ArcA/ArcB two-component regulatory system, which represses bioluminescence in *V. fischeri* and is thought to be activated by reducing conditions. Mutants lacking *arcA* or *arcB* can be a hundred- to a thousand-fold brighter than their parent strain in batch culture, underscoring their importance. One important open question is the relative importance of oxygen *per se* versus other oxidants in *lux* regulation. Reactive oxidants and/or alternative respiratory electron acceptors may play regulatory roles, although these distinctions are not yet clear.

Ecological Role(s) of Bacterial Bioluminescence

The question of why bacteria produce bioluminescence is both centrally important and difficult to answer. Many interesting hypotheses have been proposed, and it is difficult to rule many out entirely. It is important to keep in mind that the answer is likely to be different for different bioluminescent bacteria and that even for a single bacterium there may be more than one selective advantage for producing bioluminescence. Indeed, as discussed below, bioluminescence appears advantageous to *V. fischeri* on more than one level. The selective pressures on bioluminescence are likely to vary depending on context, and while one can argue that regulation should tune *lux* expression to the contexts where it is beneficial, most studies of bioluminescence and its regulation have been conducted under artificial experimental conditions (e.g., batch cultures growing on rich media in shake flasks). Taken together, our understanding of the real-world significance of bacterial bioluminescence is certainly incomplete, yet it remains a topic of great interest.

Before considering the selective advantages for bacteria to express bioluminescence, it is useful to consider the costs that must be balanced against any benefits. LuxAB can comprise 5% or more of the protein in bright cells, regenerating the aldehyde substrate requires hydrolysis of ATP (Fig. 1), and the consumption of oxygen and reducing equivalents might compete with energy-generating aerobic respiratory pathways. Consistent with luminescence coming at a price, researchers have long noticed that dim or dark mutants arise during prolonged culture, leading to speculation that in the absence of natural selection to maintain luminescence, it is evolutionarily lost for being energetically too expensive. It now appears that many such spontaneous dim mutants were probably regulatory in nature, thus simultaneously changing multiple phenotypes other than luminescence; however, a defined dark $\Delta luxCDABEG$ mutant outcompeted its isogenic wild-type parent in a carbon-limited chemostat, demonstrating a disadvantage to luminescence in at least one condition. On the other hand, bioluminescent bacteria, particularly members of the Vibrionaceae, seem well suited to lifestyles of feast and famine, growing rapidly in relatively nutrient-rich conditions and surviving through low-nutrient oligotrophic waters long enough to find another feast. It is possible that when bioluminescence is induced, its energetic costs are not all that important to the bacteria given an abundance of growth substrates.

The benefits of the Lux system could derive from any of its products. Understandably, most attention has focused on the light generated, but luciferase also consumes oxygen and reducing equivalents, and hypotheses centered on the potential importance of these activities have been proffered. For example, it has been proposed that by consuming reducing equivalents, luminescence may effectively scavenge small amounts of oxygen to help support fermentative growth by recycling NAD^+ without the need to give up a valuable organic fermentation product. This concept of supporting fermentation is consistent with the observation that luciferase has a very high affinity for oxygen, and can reduce it in low-oxygen environments where aerobic respiration is relatively ineffective anyway. At least in *V. fischeri* however, regulation is the opposite of what one would predict based on this hypothesis, as the *lux* genes are repressed by the same regulatory system that promotes many fermentative pathways. Rather, in *V. fischeri*, the *lux* genes appear up-regulated under highly aerated conditions, which is more consistent with the proposal that luciferase benefits cells as a defense against oxidative stress, either by minimizing the production of reactive oxygen species by or near the cell or by generating a reduced cytoplasmic environment that is more resistant to oxidative damage.

Complicating matters, as noted above luciferase can generate H_2O_2 when it is limited for aldehyde, and thus in some conditions luciferase might prime a response to H_2O_2 and other reactive oxygen species. Similarly LuxAB-generated H_2O_2 might be a virulence factor, doing more damage to nearby host cells than to the bacteria. However, even if the “dark reaction” production of H_2O_2 is important in some situations, it does not explain the evolution of luciferase’s light-generating capacity.

To find the importance of light-production *per se* we might ask where bioluminescence is produced in nature. For members of the Vibrionaceae, bioluminescence has been observed in several “light-organ” symbioses with animals, and here an understanding of host ecology can explain benefits to the bacteria. Squid and fish with symbiotic light-emitting tissues employ the bioluminescence for a range of uses, including lures for prey, intra-species signals, and a camouflaging strategy called counter-illumination. The simple argument is that these symbioses represent mutualisms, and if hosts are supporting symbiotic bacteria in exchange for bioluminescence, then by benefiting their hosts the bacteria could effectively be benefiting themselves. Although in most cases the bacterial symbionts from the Vibrionaceae have retained an environmental lifestyle outside the host, symbionts of certain anglerfishes have reduced genomes and appear to have evolved a dependence on the host, underscoring the support that hosts may provide.

The light-organ symbioses between sepiolid squids and *V. fischeri* or *V. logei* have received considerable attention, particularly the model of *V. fischeri* and the Hawaiian bobtail squid *Euprymna scolopes*. This nocturnal shallow-water host squid has a bioluminescent “light organ” with light provided by *V. fischeri*, and it is thought to use the light in a counter-illumination strategy, matching the down welling moon and star light with its own dim ventrally oriented light. In this way, the squid may obscure their silhouette from other animals beneath them in the water column. Moreover, the squid expel some of the bacteria back into the environment each day, resulting in higher *V. fischeri* populations where the squid live. In this case, the benefit of bioluminescence for the bacteria can be rationalized as a contribution to a mutualistic symbiosis; helping a host that supports the bacterial population in return.

Interestingly, there is another layer of advantage for *V. fischeri* symbionts of *E. scolopes*, illustrated by the observation that dark mutants are attenuated in the ability to colonize the light organ. This colonization defect is apparent even when a $\Delta\text{luxCDABEG}$ mutant co-colonizes a host with a luminescent wild-type strain, so it seems unlikely that this effect could be explained entirely by the host sanctioning a dark infection. This relative fitness defect of a dark mutant in the light organ is the opposite of what has been observed in a carbon-limited chemostat, where (as noted above) a dark mutant can outcompete the bioluminescent wild type. Understanding the light-organ environment and the physiology of the symbionts in this environment may hold a key to understanding growth conditions in which the Lux system is inherently advantageous, which would provide enormous insight into the evolution of bioluminescence.

In addition to light-organ symbioses, *Vibrio* species are frequently found in the enteric tracts of hosts, which typically contain mixed consortia of many bacteria and provide them with a relatively rich set of resources compared to the surrounding waters. If populations of bioluminescing bacteria are high enough in gut tracts, then the fecal matter released by hosts may actually glow, and it has been proposed that this property might attract other marine animals to eat the feces and thus return the bacteria to the privileged environment of a host gut. This simple idea is compelling and could explain the widespread distribution of luminescent bacteria in fish guts even in areas without known light-organ symbioses.

Another large-scale but intermittent and mysterious phenomenon called “milky seas” appears to result from large swaths of bioluminescent bacteria near the ocean surface. Covering areas measuring up to thousands of square kilometers, the persistent luminescence from “milky seas” has been reported by ships and corroborated by satellite imaging. The duration of these luminescent patches, which can extend for hours or days, seems more consistent with bacterial bioluminescence than with other known sources of marine luminescence. How bioluminescent bacteria could achieve high enough populations to produce the amount of light emitted is not known, but speculation and anecdotal evidence have suggested blooms of phytoplankton (or some other organism) that can serve as a host for a bioluminescent bacterium. *Vibrio campbellii* has been suggested as a candidate bioluminescent bacterium able to exploit phytoplankton blooms, but whether this is the case and whether bioluminescence is in some way beneficial in this context require further exploration.

What of bioluminescent bacteria other than members of the Vibrionaceae? As noted above, bioluminescent *Photobacterium* species are symbionts of insecticidal nematodes and are responsible for glowing insect cadavers. *Photobacterium* symbionts play important roles for their nematode hosts, helping to kill and digest insect victims and contributing to normal development in their host’s life cycle; however, their bioluminescence is not required for this symbiosis in at least one symbiont-host combination, and its purpose is unclear. It has been proposed that the luminescence from a dead insect might attract other potential insect victims, or alternatively it might deter larger organisms from eating the dead insect, which would potentially represent a dead end for the *Photobacterium* and

nematode. Bioluminescence in *Photorhabdus* is subject to regulation, and notably it is among the properties controlled by a bi-stable regulatory switch that results in two distinct phenotypic variants. The bioluminescent variant retains its symbiotic properties with insecticidal nematodes, implicating a role in this context.

The ecological importance of luminescence in *Shewanella* species is perhaps even less clear. *Shewanella hanedai* and *Shewanella woodyi* have been isolated from seawater, sediments, and from the surfaces of some marine animals, but there are no known light-organ symbioses, nor is there a natural environment in which their bioluminescence has been documented. Unlike members of the Vibrionaceae, which tend to be facultative anaerobes and are often found in animal enteric tracts, *S. hanedai* and *S. woodyi* appear to rely on respiratory growth and are associated with animal or abiotic surfaces rather than guts. Thus, the concept of luminescence serving to attract animals to eat fecal matter, thereby returning the bacteria to an enteric tract, does not seem to apply. The *lux* genes appear to have moved into *S. hanedai* and *S. woodyi* from the Vibrionaceae relatively recently, and perhaps the *lux* operon conferred a physiological advantage unrelated to the light emission that has been selected for in the vibrios.

Although many proposed roles for bioluminescence appear viable in at least some systems, a few appear unlikely. For example, a series of indirect observations led to the hypothesis that luciferase could allow ATP generation in the absence (or inhibition) of cytochromes, and this hypothesis has led to the occasional claim that luciferase can replace cytochromes. Although this is thermodynamically feasible, an ATP-generating mechanism theorized by this model has never been shown, and thirty years after it was suggested, clear experimental evidence that luciferase can replace cytochromes remains lacking. In another example, it has been proposed that luminescence might provide cells a benefit by activating light-dependent photolyase-mediated DNA repair. Although experimental data suggest luciferase-generated light *can* activate photolyase in this way, the arguments against this process being ecologically relevant seem overwhelming. In these cases and others however, even if the proposed role of luminescence is doubtful, the observations merit further exploration.

Applications of Bacterial Bioluminescence in Research and Biotechnology

The bioluminescence produced by LuxAB can be detected with great sensitivity, making it attractive for a number of applications. For example, bioluminescent bacteria are used in toxicity tests wherein compounds are added to cultures and the effect on bioluminescence is measured. This approach has advantages of simplicity and rapid output over other assessments of toxicity that measure effects on metabolic activity or loss of viability. If a compound kills bacterial cells or broadly blocks their metabolism, the loss of luminescence may be the fastest possible measure of this effect. Most often, cultures of *V. fischeri* are sold and used for this purpose.

Bioluminescence has also been exploited by introducing the *luxCDABE* operon into non-native bacteria. For example, in one general approach, phages (viruses that infect bacteria) have been engineered to carry the *luxCDABE* operon, such that when the phage injects its DNA into a specific target bacterium, that bacterium will bioluminesce. In order to produce light, the target bacterium must be capable of expressing the *lux* genes and able to provide LuxAB with substrates, and as a result such engineered phages can be used to detect metabolically active cells of a specific bacterium in a sample, whereas other (e.g., antibody-based) approaches may detect both live and dead cells. This technology has been combined with the addition of various antibiotics to test whether particular antimicrobials affect a target bacterium. This luminescence-based strategy holds potential to be much faster than traditional antibiotic-sensitivity testing that is based on growth inhibition.

The *luxCDABE* operon or simply the *luxAB* genes also have been used in a wide range of bacteria as reporter genes fused to transcriptional promoters of interest. Researchers probing the transcriptional regulation of a particular gene may fuse its promoter to *luxCDABE*, allowing them to use bioluminescence as a convenient readout of promoter activity. Sometimes *luxAB* is simply used rather than the entire operon, and in this case aldehyde substrate must be provided at the time bioluminescence is to be measured, and consideration should be given to the possibility of H_2O_2 production from the “dark reaction” in aldehyde-limited cells. Through such reporter studies, the environmental conditions or transcription factors controlling expression of a particular gene or operon can be discovered and assessed. Viewed from another angle, the same basic approach can be used to generate bioluminescent “bioreporters”, wherein a particular environmental condition can be assessed based on known effects on a transcriptional reporter. For example, if the *lux* genes are placed in a bacterium under control of a transcriptional promoter that is activated in response to phosphate limitation, cells will induce luminescence when available phosphate is low. In this way, bacteria have been engineered to bioluminesce only in response to a particular pollutant, stress, antibiotic, or other cue. This technology can be applied in complex samples and has advantages when biochemical detection of a particular compound is difficult or somewhat ambiguous. Because bioreporters are based on living cells, they have the advantage that they can be used to assess not only the presence of particular molecules but also their bioavailability.

Another application of the *luxCDABE* operon is to constitutively express it in otherwise dark bacteria to make them luminescent, thereby allowing the cells to be detected and tracked in a sample based on their bioluminescence. This approach became much more attractive with the advent of intensified charged-coupled device (ICCD) camera detectors, which allow researchers to visualize the location of light-producing bacteria even in what appears visually to be an opaque tissue. For example, when mice are infected internally with transgenic *Salmonella enterica* carrying the *lux* operon, the mice do not become visibly bioluminescent, but an ICCD camera can detect the photons emitted and track the location of the pathogen in host tissues. This use of *luxCDABE*, along with its use as a reporter, further illustrates that acquisition of a single locus is sufficient to render many phylogenetically diverse bacteria bioluminescent.

While most of the above applications have used naturally bioluminescent bacteria or their *lux* genes, in some approaches the Lux system has been engineered to maximize its utility in other organisms. For example, the *lux* genes have been reconstructed to better match normal codon usage in various hosts of interest, the *luxA* and *luxB* genes have been fused to encode a single protein, the *lux* genes have been expressed on smaller transcripts in organisms that typically do not express genes as operons, and alternative or additional pathways to FMNH₂ synthesis have been added to certain hosts. Such tweaks to the original *lux* system have made it more useful in a broader range of organisms.

Bioluminescent Bacteria in Education

Given the tractability of bacteria as research subjects and the intriguing attraction of bioluminescence, it is not surprising that bioluminescent bacteria have found their way into classrooms and laboratory demonstrations. In classes where specific types of bacteria are targeted for isolation from the environment, bioluminescent strains are a favorite. As noted above, many bioluminescent bacteria are found in marine waters or associated with marine animals such as fish. As a general approximation, coastal seawater contains about one bioluminescent colony-forming unit per ml when plated on a rich salty medium, and potential environmental isolates can be concentrated by passing several milliliters of coastal seawater through a filter with a 0.2–0.4 µm pore size. Alternatively, students can isolate bioluminescent bacteria from fresh marine fish or squid acquired at a local market, provided the meat has not been disinfected. Fortunately, many bioluminescent marine bacteria are relatively fast growing on rich media when incubated at temperatures similar to the environments from which they came, so while a plate may be crowded with various microbes the bioluminescent bacteria typically are not overgrown by others. By taking isolation plates into a darkroom, students are able to pick out target colonies, sometimes with slightly different shades and intensity of blue light. Students can readily narrow the identity of their isolates using traditional microbiological techniques or molecular phylogenetics.

Bioluminescence is also used in experiments that demonstrate molecular cloning methods. In this case, instructors take advantage of the fact that all the *lux* genes necessary for bioluminescence are clustered together on a single locus and therefore can be cloned on a single DNA fragment. The *lux* operon from *V. fischeri* is a favorite for cloning, because in many strains the sequences flanking the boundaries of the *lux* locus contain recognition sites for the restriction enzyme *Sall*, such that digestion of *V. fischeri* genomic DNA with *Sall* liberates a distinct *lux*-specific DNA fragment with short single stranded ends suitable for cloning into a plasmid that has likewise been digested with *Sall*. Moreover, the workhorse bacterium for molecular cloning, *E. coli*, is able to bioluminesce once transformed with *lux*-containing plasmids, provided it is grown at temperatures compatible with *V. fischeri* growth (e.g., 22–28°C).

Conclusions

Extensive research has unraveled many of the mysteries of bacterial bioluminescence. The bacteria, genes and enzymes underpinning this phenomenon have been elucidated in many respects, and our understanding has enabled us to exploit bacterial bioluminescence in basic research, biotechnology, and education. Yet new details continue to be filled in and many important questions remain open and unanswered. Among these, the central question of the role bioluminescence plays in bacterial ecology still invites speculation and further testing. While the central features of the *lux* system are well conserved, differences at the biochemical and regulatory level suggest that there may not be a single answer to this question, and bioluminescence may confer a fitness advantage on different bacteria for different reasons. Studying the expression and impact of bioluminescence in natural environments for the bacteria is a promising approach for further exploration. Future studies of bioluminescent bacteria in ecologically relevant contexts will be bolstered both by model systems amenable to laboratory experimentation and by methods for studying bacteria in the environment. Such approaches along with deeper molecular insights into the evolution and biochemistry of the Lux system will add to our already rich understanding of bacterial bioluminescence.

Bacterial Cell Cycles and Division[☆]

N Nanninga, Universiteit van Amsterdam, Amsterdam, The Netherlands

© 2019 Elsevier Inc. All rights reserved.

Glossary

Cell division genes Genes that encode for proteins that specifically function during the division process.

Constriction, septation Mode of cell envelope invagination during division. During constriction all envelope layers move inwards simultaneously and the daughter cells move gradually apart; septation involves the ingrowth of the cell envelope forming a T-like structure.

Cytokinesis In prokaryotes, the process of cell division. By contrast, in eukaryotic cells division also includes mitosis.

***daw* cluster** The cluster of genes involved in division (*d*) and cell wall (*cw*) synthesis. In many bacteria this cluster is evolutionary conserved.

Divisome The macromolecular complex that carries out division at the cell center.

Fts proteins Cell division proteins encoded by *fts* genes. In temperature-sensitive (ts) cell division mutants, division is blocked and, because cells continue to grow, filaments (f) are formed.

Minicells Small DNA-less cells that arise through divisions at the poles of rod-shaped bacteria.

Multifork replication More than one round of DNA replication ongoing in one and the same chromosome. It arises when the doubling time of the culture is shorter than the duration of the DNA replication period.

Penicillin binding proteins Proteins involved in peptidoglycan assembly outside the cytoplasmic membrane. They bind specific antibiotics.

Peptidoglycan Covalently closed structure that has the shape of a bacterium. It is composed of glycan chains, which have peptide side chains. Cross-linking through the peptide side chains provides for a strong network.

Potential division sites Cellular sites beyond the nucleoid areas. They occur at cell pole or in the cell center, provided that the nucleoids have segregated.

Introduction

Proliferation of cells, whether pro- or eukaryotic, requires duplication of cytoplasm and genetic material (DNA) and the subsequent distribution of the new genomes over two daughter cells. All molecular components should have been duplicated before fission. Though the above description applies to all cells, some prokaryotes (bacteria) show features that are essentially different from their eukaryotic counterparts. It is important to appreciate these differences because, as will be shown below, they bear on concepts pertaining to the progression of the cell cycle. For instance, is a newborn cell completely new or even is there a cell cycle?

According to the standard view, the eukaryotic cell cycle is punctuated by four sequential periods: the G1 period in which cells grow and prepare for DNA replication, the S-period in which DNA replication takes place, the G2-period where cells prepare for mitosis, and finally, the M-period during which chromosomes become compact, align in the cell center, and segregate producing new daughter cells. The fission of cells is termed cytokinesis. Note that in the eukaryotic field cell division encompasses mitosis and cytokinesis, whereas in prokaryotes cytokinesis is commonly designated as cell division alone. Of the many prokaryotic species, only a few bacteria have been or are being studied in detail. However, cell cycle studies on archaea are strongly emerging. For bacterial cell division, a distinction should be made, though not fundamentally, between Gram-positive species [*Bacillus subtilis*, *Enterococcus hirae* (formerly called *Streptococcus faecalis* and *S. faecium*), *Streptococcus pneumoniae*] and Gram-negative species [*Caulobacter crescentus* and *Escherichia coli*].

To date, *E. coli* has been studied most intensively with respect to the cell cycle, though closely followed by *B. subtilis* and *C. crescentus*. Here we will focus mainly on *E. coli* (Figure 1), because *B. subtilis* and *C. crescentus* have been treated elsewhere (specify). Some interesting features have emerged from the study of archaea, which differentiate them from bacteria and which sheds a broader light on prokaryotes in general.

The *E. coli* cell cycle is marked by three main events: the DNA replication cycle, cellular growth and the division cycle. Increase in cell size in rod-shaped organisms is manifested as cell elongation, which is terminated by fission, that is, the ingrowth of the cell envelope. As envelope growth is a dominant feature of cell growth the focus will be on its shape-maintaining peptidoglycan layer. Below the employed terminology and the temporal relationship between the DNA replication cycle and the division cycle will be described.

[☆]Change History: August 2014. N Nanninga introduced small edits in the text of the article including Figures and Further Reading.

The Cell Cycle of *Escherichia coli*

The Cell Cycle Periods of *E. coli* Differ from Those of Eukaryotes

How do the standard eukaryotic cell cycle periods compare with those of a bacterium like *E. coli*? In both cases, the lengths of the periods are affected by growth conditions. In eukaryotes the duration of G1 is directly related to the richness of the growth medium, the other periods being somewhat independent; however, in *E. coli*, the growth conditions specifically affect the position of the DNA replication period within the division cycle. In slowly growing cells, that is, cells growing in a relatively poor medium, an equivalent of a G1-period can be distinguished. This is followed by an S-like period denoted as C. However, a striking difference with eukaryotes can now be observed: in *E. coli* DNA replication and DNA segregation go hand in hand. So in fact, S=M. Consequently, bacteria lack classical mitosis. In *E. coli* the C-period is followed by the D-period, being defined as the period between termination of DNA replication and cell division. During the D-period cells prepare for and carry out cytokinesis. Thus, the G2- and M-periods have no direct counterparts in *E. coli*. As will be shown below archaea are to some extent reminiscent of eukaryotic cells.

The Division Cycle and the DNA Replication Cycle Do Not Coincide

The duration of C is affected by growth conditions. *E. coli* B/r cells that grow with doubling times (Tds) of 20–60 min at 37 °C have a C-period of 40 min and a D-period of 20 min. This length of D appears to be the minimal time span required to build the division apparatus or divisome (see below). Similarly, the shortest duration of C is about 40 min. Thus, under given growth conditions at least 60 min (C+D) have to elapse before fission is completed. Application of this rule for a range of doubling times is graphically presented in Figure 2.

Figure 2 Temporal relationship between DNA replication period (C) and the division cycle in *Escherichia coli* B/r at doubling times (Tds) from 20 to 80 min at 37 °C. B, period between cell birth and initiation of DNA replication. D, period between termination of DNA replication and cell division. The C-period is shown as a brown bar. An interrupted brown bar denotes DNA replication before cell birth at the extant cycle. In this scheme C=40 min and D=20 min. I₁, initiation of DNA replication belongs to the extant division cycle. I₂ and I₃, subsequent initiations of DNA replication. The frequency of initiation equals Td. The green line depicts an unreplicated chromosome. The red dot represents an activated origin of replication. At Td=50 min, one quarter of the chromosome has been replicated at birth. At Td=20 min, a newborn cell contains two chromosomes that have been replicated halfway. Initiation of DNA replication follows immediately after birth at the four origins. This happens before the ongoing round of replication has been completed. This results in multifork replication (cf. Figure 3). How one arrives at the chromosome configuration at cell birth is shown below. At Td=20 min, 20 min are needed for the preparation of division (D-period), which is preceded by C=40 min. Thus I₁ begins at –40 min as indicated. After 20 min at –20 min the chromosome is replicated halfway. At the same time (after one Td) a new round of DNA replication starts at I₂. One Td later chromosomes have segregated and are at the same time replicated halfway. New initiations start at I₃. Note that cells become bigger as Tds decrease. C and D values apply for *E. coli* B/r grown at 37 °C. For K12 strains they can be different.

Let us start with a Td of 60 min. Since $C+D$ equals Td, DNA replication must start at cell birth. At slower growth rates ($Td > 60$ min) a period without DNA synthesis after birth is seen, and it becomes longer as Td increases. In the example, the period is 20 min ($Td = 80$ min; Figure 2). When $C+D < Td$, for instance, when Td is 50 min the duration of the division cycle is too short to complete DNA replication and division. The problem is solved by DNA replication beginning in the previous cycle. It can be seen that DNA replication has to start 10 min before cell birth (Figure 2). It will be appreciated that this leads to a newborn cell whose chromosome is one quarter replicated. Conceptually, this has an important consequence: a newborn cell does not start out with a new round of DNA replication.

Multifork Replication

What happens if $C \leq Td$? For example, if Td equals 20 min (when $C+D = 60$ min). To solve this problem DNA replication initiates at cell birth two cycles earlier as indicated (I_1 in Figure 2). A new initiation takes place every 20 min in line with Td. These subsequent initiations have been indicated as I_2 and I_3 in Figure 2. As a result, the newborn cell of the extant cell cycle has its chromosome not only fully replicated (two chromosomes in a newborn cell) it also has been engaged in DNA replication for 20 min. Moreover, a new round of DNA replication starts at birth (I_3 in Figure 2). Thus 5 min after birth, the bacterial chromosome is involved in two DNA replication cycles at one and the same time. This phenomenon has been termed multifork replication (Figure 3).

In eukaryotes multifork replication does not occur, presumably because chromosome compaction during mitosis precludes DNA replication. It is also for this reason that in eukaryotes the DNA replication cycle is contained within the ongoing division cycle. In bacteria, as outlined above, this is not obligatory. The fact that in bacteria the DNA replication cycle and its division cycle do not always coincide implies (as mentioned above) that a newborn bacterial cell is not completely new. Clearly, bacteria can also do without an identifiable G1-period. This has led to the notion that bacteria continuously prepare for the initiation of DNA replication, not only during DNA replication but also during D. It implies that the bacterial G1-period has no specific functional meaning; it simply arises because $C+D < Td$. It has been argued that the same reasoning would apply to the G1-period in eukaryotes. This common concept for pro- and eukaryotes has been called the continuum model by Cooper. The division cycle can be conceived of as a means for a cell to maintain and enlarge its molecular fabric to allow replication of its genome. Thus, while mass continues to be made, the bacterial chromosome replicates, independently of division. So one may ask, do cells really cycle?

As implied above (Figure 2), cellular DNA content increases with the growth rate. Roughly, there is a relationship between cell size and the number of chromosomes that initiate DNA replication. Thus, dependent on growth conditions there can be a dramatic difference in cell mass and DNA content (Figure 4).

DNA Replication Cycle

DNA Replication Cycle in *Escherichia coli*

In the standard description of the eukaryotic cell cycle the G1-period encompasses protein synthesis including preparation for DNA replication during the S-period (see however, the continuum model above). A separate description of the bacterial equivalent (B-period) does not seem warranted because it often is not distinguishable (dependent on growth conditions; see above).

Figure 3 Linear (left, cf. Figure 2) and circular (right) representation of a replicating chromosome. *oriC*, origin of DNA replication; *terC*, terminus of DNA replication. RF, replication fork. The circle shows bidirectional replication. Below, multifork replication is shown.

Figure 4 Electron microscopical images of thin sections of two *Escherichia coli* cell halves. The left and right cells have been grown at Td's of 21 and 150 min, respectively. The mean respective genome equivalents are 4.6 and 1.2. The left cell contains four replicating chromosomes at division, the right cell one. Scale = 1 μ m. N, nucleoplasm.

It has been early recognized that initiation of DNA replication takes place at a defined cell mass (initiation mass). Of course, the challenge has been to translate this rather vague notion into molecular terms. In *E. coli*, the protein DnaA has been invoked as a positive regulator of initiation of DNA replication. DNA replication in *E. coli* starts at a fixed DNA sequence on the chromosome (*oriC*) and progresses bidirectionally toward the terminus *terC* (Figure 3). *OriC* is a 258-bp sequence that is flanked by other regions required for the onset of DNA replication. Of particular importance are so-called DnaA boxes that recognize the DnaA protein. DnaA becomes active when it binds ATP. When sufficient DnaA-ATP is available for occupation of the DnaA boxes, melting of the DNA double strands of the origin takes place, allowing replication proteins to bind. There are additional DnaA boxes on the chromosome but their function is not known. Conceivably, these boxes titrate away excess DnaA to prevent premature reinitiation of *oriC*. Continued protein synthesis serves to provide new DnaA molecules for a next round of replication.

An additional mechanism has been invoked that prevents premature initiation of DNA replication. This is based on the fact that newly synthesized DNA is hemimethylated in contrast to mature DNA, which is fully methylated. Hemimethylated DNA containing GATC sites becomes sequestered by a protein appropriately called SeqA, thus preventing reinitiation of DNA replication. The duration of the re-replication block is in the order of one third of Td. Presumably, this period in combination with a limited amount of DnaA is sufficient to prevent reinitiation prematurely.

DNA Replication Cycle in Archaea

Bacteria and archaea, though prokaryotes, differ from one another with respect to DNA replication and possibly DNA segregation. This supports the inference that archaea are closer to eukaryotes than to bacteria. It should be emphasized, however, that this similarity is on the level of genes and macromolecules and not on the level of cellular organization. Though a limited number of archaea have been investigated some interesting features have emerged. For instance, in hyperthermophile *Sulfolobus* spp., which belong to the archaeal phylum Crenarchaeota the chromosome contains three different origins. These initiate simultaneously, though termination appears variable in time. This is reminiscent of the multiple origins in a eukaryotic chromosome. In *S. solfataricus* pairing of replicating as well as postreplicating chromatids have been observed. This suggests the presence of genuine G₂-period in this organism. Whether chromosome compaction precedes DNA segregation remains to be seen. However, it seems likely that DNA replication and DNA segregation do not run in parallel as in *E. coli*.

Division Cycle

Rod-shaped cells like *E. coli* elongate before they divide. This implies growth of the covalent peptidoglycan layer and insertion of new components in the non-covalent inner and outer membrane. This in turn is followed by division-specific peptidoglycan synthesis.

Peptidoglycan Synthesis During Cell Elongation

The cell envelope of *E. coli*, as in all Gram-negatives, is composed of three layers. From outside to inside these are the outer membrane, the peptidoglycan or murein layer, and the inner- or cytoplasmic membrane. Because of its rigid nature the peptidoglycan-containing cell wall serves as an exoskeleton, which maintains the shape of the cell. Its strength prevents cellular disruption due to osmotic pressure and also plays an active role during the constriction process. Recent research has revealed the occurrence of the actin-like cytoplasmic protein MreB directly underneath the inner membrane. Impairment of MreB leads to spherical cells, suggesting a functional interplay between MreB and peptidoglycan assembly in establishing and maintaining cell shape.

Precursors of building blocks for the peptidoglycan layer are produced stepwise in the cytoplasm. The final cytoplasmic products are lipid I and II, which are made by the enzymes MraY and MurG, respectively. MraY, a translocase, is an integral membrane protein that binds UDP-MurNAc-pentapeptide to undecaprenyl phosphate forming lipid I. MurG, a transferase is tightly associated with the cytoplasmic side of the inner membrane. It adds UDP-GlcNAc to lipid I producing lipid II. An unknown flippase activity transfers the disaccharide moiety of lipid II to the periplasmic side of the inner membrane, where it serves as a substrate for penicillin binding proteins (PBPs). Elongation of the glycan chains of existing peptidoglycan is carried out by a transglycosylase activity and cross-linking of peptide side chains is due to a transpeptidase activity. Some PBPs such as PBP1a and PBP1b are bifunctional and perform

Figure 5 Protein machine (elongasome) involved in cell elongation. It encompasses components in cytoplasm, inner membrane, and nascent peptidoglycan. IM, inner membrane; OM, outer membrane; PG, peptidoglycan layer. The peptidoglycan synthesizing machinery including MurG, MraY, PBP1b and PBP2 is positioned by MreB located underneath the inner membrane. This model integrates data from *Escherichia coli* and *Caulobacter crescentus*.

both activities. PBP2 is monofunctional with only transpeptidase activity. PBP2 is essential for the cells' rod shape, because mutations or binding by the PBP2-specific antibiotic mecillinam turns rods into spheres. Light microscopic fluorescent studies have shown that PBP1b and PBP2 are dispersed along the lateral wall (like MreB), with additional label at the site of constriction (see also below). Another rod-shape determinant is RodA, a transmembrane protein, whose biochemical function is not yet known. Recently, an additional rod-shape determinant, RodZ, has been found. It is a membrane protein with cytoplasmic and periplasmic domains. Possibly, connecting peptidoglycan-associated activities across the inner membrane (Figure 5).

Increasing evidence points to the presence of macromolecular complexes that connect cytoplasm and periplasm in order to carry out peptidoglycan synthesis at many site along the cells' length. These complexes seem to be randomly located with the actin-like MreB protein(s) serving as a scaffold (Figure 5). Such an arrangement can explain why a diffuse incorporation of peptidoglycan precursors has been found in earlier studies. Older studies have also shown that outer membrane assembly is a random process along the cell length. Originally, it was thought that MreB polymers are arranged in helical fashion underneath the inner membrane. However, recent evidence indicates that the helical arrangement has been caused by the presence of a fluorescent protein tag at N-terminal end of MreB. Whether this outcome bears on other studies with fluorescent protein tags remains to be seen.

Though we have focused on PBPs with synthetic activities, there are numerous other enzymatic activities that lead to remodeling and recycling of peptidoglycan. In this sense, Figure 5 represents only a first approximation of the *in vivo* situation.

The Divisome and Divisome Subassemblies

Most cell division proteins have been discovered through the phenotypes of temperature sensitive cell division mutants. At the nonpermissive temperature cells grow as filaments, thus revealing defects in the division process. Many cell division proteins have the prefix Fts, meaning filamentation-thermosensitive. Genetic studies have been complemented by microscopic labeling studies, both by electron microscopical immunogold labeling (Figure 6) and fluorescent light microscopy (Figure 7).

Cytokinesis is carried out by a protein machine called the divisome, which contains about 20 different proteins. The majority of them are specific for the divisome, others are also active during cell elongation. These proteins are located in different cellular compartments and are cytoplasmic proteins, integral transmembrane proteins, or periplasmic proteins with a membrane anchor. Recently, a protein complex has been identified (Tol-Pal), which connects the divisome to the *E. coli* outer membrane.

The first protein to arrive at the site of division is the cytoplasmic protein FtsZ (Figure 6). It is a tubulin homologue with GTPase activity. FtsZ occurs in thousands of copies per cell. Potentially, FtsZ forms one or more ring-like polymers underneath the cytoplasmic membrane in the cell center. The exact *in vivo* conformation of the FtsZ polymer(s) is (are) not known. It clearly is a dynamic structure, as demonstrated by photobleaching experiments. The Z-ring must decrease in circumference during the constriction process, without losing its integrity. Whereas FtsZ occurs in thousands of copies in a cell, other proteins like FtsQ (Figure 7) are present in only about 50 copies per cell. Thus, such proteins cannot participate in forming a ring that spans the circumference of the cell. Presumably, FtsQ and other low-copy number proteins are grouped into divisome subassemblies, which decorate extended FtsZ polymers (Figure 8).

Recent investigations have revealed the temporal sequence of divisome biogenesis. The assembly of a functional divisome takes place in two steps. In the first step, the cell division proteins FtsA, ZipA (Z-interacting protein A) and ZapA (Z-associated protein A) bind and stabilize an initial FtsZ-ring. In the later stage, the other cell division proteins are recruited, including FtsK, FtsQ, FtsL, FtsB,

Figure 6 Electron microscopic image of immunogold labeled FtsZ in a thin section. Reproduced from Nanninga N (1998) Morphogenesis of *Escherichia coli*. *Microbiology and Molecular Biology Reviews* 62: 110–129.

Figure 7 Fluorescent image (right) of FtsQ-GFP labeled live *Escherichia coli*. Left: phase contrast image. See attached film clip GFP-FtsQ. Courtesy of Dr. T den Blaauwen.

FtsW, FtsI (PBP3; penicillin binding protein 3), FtsN, and AmiC. Presumably, a subassembly is composed of these proteins (Figure 9). Remarkably, a complex of FtsB, C and L, can exist outside the divisome. The function of the various proteins is largely unknown. FtsA is a member of the actin superfamily, FtsK has a role in separating chromosomes after termination of DNA replication, FtsI is a transpeptidase, and AmiC an amidase. The latter two proteins emphasize the importance of peptidoglycan synthesis during division.

Potential Division Sites and Site Selection

Although it is customary to think that cells split in the middle, additional potential division sites exist at the cell poles (Figure 10). As depicted here, division takes place at regions that are not near the nucleoid (nucleoid occlusion; see ‘Cell Cycle Regulation’). Interestingly, polar divisions occur in thermosensitive *min* mutants and result in the so-called minicells. These are devoid of DNA, though not of ribosomes, thus can still carry out some residual protein synthesis. The phenomenon of minicell production indicates the existence of a system to prevent polar divisions. It is known as the Min system and includes different proteins. The protein MinC inhibits polymerization of FtsZ at the cell poles. MinC is recruited to the membrane by the ATPase MinD in its ATP-bound form. Binding of MinD to the membrane is released by interaction with MinE, which causes ATP hydrolysis. MinE is specifically active at the cell center, thus preventing inhibition of FtsZ polymerization by MinC. Remarkably, the polar topology of these reactions is achieved by oscillation of MinD from pole to pole. The time course of one oscillation is in the order of one minute. The Min system as described for *E. coli* is not found in *B. subtilis* or *C. crescentus*. Interestingly, Min proteins (and FtsZ) have been found in chloroplasts as well as in some mitochondria, which emphasizes the endosymbiotic origin of the latter organelles.

Though the mechanism of division site selection is not fully understood, regulating elements include the sensing of the cellular position of the nucleoid (see also below) and the inhibition of polar divisions by the Min system.

Figure 8 The division process in *Escherichia coli*. First the FtsZ ring with associated proteins (FtsA, ZapA and ZipA; not shown) is formed. Next divisome subassemblies are positioned. During constriction the subassemblies approach each other, whereas FtsZ leaves the ring. Note that the various components have not been drawn to scale.

Figure 9 Protein composition of a divisome subassembly. The divisome subassembly spans cytoplasm, inner membrane (IM), peptidoglycan layer (PG), periplasm and outer membrane (OM). It interacts with an FtsZ scaffold, which is reinforced by the cytoplasmic proteins FtsA, ZapA, and ZipA. The latter is anchored to the inner membrane. Specific components of the divisome subassembly are FtsB, FtsI, FtsK, FtsL, FtsN, FtsQ, and FtsW. Most of the proteins have their main domain in the periplasm as depicted. Note that FtsW is membrane-embedded. The cytoplasmic domain of FtsK functions in DNA segregation. Tol-Pal connects the subassembly to the outer membrane. Also present are Mray, MreB, and MurG, which can also be found in the elongasome (cf. Figure 5).

Figure 10 Potential division sites in a rod-shaped cell. Division takes place where there is no physical obstruction of the nucleoid, that is at poles and in the cell center. Normally division only occurs in the cell center. However, when the Min system is impaired a minicell is formed at a pole. Division starts by the positioning of a Z-ring (green) composed of polymerized FtsZ.

Peptidoglycan Synthesis at the Divisome

Constriction is not simply the pulling inwards of the envelope by an FtsZ-ring of a decreasing circumference. The constriction process requires local envelope synthesis at least on the level of the peptidoglycan layer. Early electron microscopic autoradiographic studies have shown that the peptidoglycan precursor ^3H -*meso*-diaminopimelic acid is especially incorporated at the site of constriction. FtsI (PBP3) is involved in divisome-specific peptidoglycan synthesis. It is the most intensively studied of all cell division proteins. Certain antibiotics, such as cephalexin, furazlocillin and aztreonam, act on this protein specifically. Inhibition of FtsI by these antibiotics or inactivation of FtsI in a thermosensitive *ftsI* mutant at the nonpermissive temperature produces filaments with aborted blunt constrictions. This is in contrast to filaments of thermosensitive *ftsZ* mutants, which have a smooth morphology. Peptidoglycan assembly does not take place at the blunt constrictions. Remarkably, inhibition of FtsI does not prevent peptidoglycan synthesis at new division sites flanking the blunt constrictions (Figure 11). This has been demonstrated by electron microscopic autoradiography and by viewing the dilution of immunogold label attached to -SH groups of D-Cys incorporated into the peptidoglycan layer. It is plausible that initial peptidoglycan synthesis at the division site is carried out by PBP2 and PBP1B as remnants of the cell elongation system. The phenotype of FtsI-impaired cells has led to an early suggestion that FtsI plays a role in a later stage of cell division. It also fits the idea that FtsI becomes recruited to the assembling divisome in a second step (see above).

The localized function of FtsI requires the presence of enzymes, which prepare the substrate prenylated disaccharide peptide (lipid II) for PBPs to act upon in the periplasm. During cell elongation these enzymes are MraY and MurG. Most likely these proteins are also present in the divisome (Figure 9). An interaction between FtsZ and MreB has recently been described.

A Gram-negative organism like *E. coli*, as outlined above, divides by constriction in the cell center (Figure 12). In a Gram-positive like *B. subtilis*, a circumferential inward-growing septum divides the new daughter cells, whereas in the latter, the cell constricts in the cell center (Figure 12). *B. subtilis* lacks an outer membrane (which affects the Gram-stain) and has a thick cell wall composed of peptidoglycan and teichoic acid as the main components. Yet, the arrangement of genes involved in peptidoglycan assembly and cell division on the respective chromosomes reveals similarity (see below).

Figure 11 Inactivation of FtsI (PBP3) halts constriction and produces blunt constrictions. Incipient division remains possible at future division sites flanking the aborted constriction. FtsZ rings (green) form and PBP3-independent peptidoglycan synthesis (PIPS) proceeds.

Figure 12 Division by constriction in *E. coli* and by septation in *B. subtilis*. During the constriction process the envelope layers invaginate together; during septation a T-structure is formed.

Figure 13 Genes involved in cell division (*d*) and cell wall (*cw*) synthesis are grouped together (*dcw* cluster) in a wide range of bacteria. In *Escherichia coli* they are located at the 2-min region of the chromosome. Genes encoding for cell division proteins are shown in red; those involved in cell wall synthesis in green. Reproduced from Mingorance J, Tamames J, and Vicente M (2004) Genomic channelling in bacterial cell division. *Journal of Molecular Recognition* 17: 481–487.

Organization of Cell Division Genes on the Chromosome

The *E. coli* chromosomal map is divided into 100 min. In this organism most cell division genes are located at 2 min. Remarkably, many genes encoding enzymes involved in the formation of peptidoglycan precursors and in peptidoglycan assembly are also situated in this region. The 2-min region is therefore also denoted as the *dcw* cluster, where *d* stands for division and *cw* for cell wall (Figure 13). This clustering suggests the existence of a global regulatory mechanism that coordinates expression of the many genes and which directs the transformation of elongation-specific to division-specific peptidoglycan synthesis. To date, little is known about division-specific gene expression. Recent genomic sequences studies have shown that the *dcw* cluster is conserved amongst bacteria. Note that archaea have no peptidoglycan and consequently, no PBPs.

Cell Cycle Regulation

The tight coordination between DNA replication and cell division requires that cell division takes place at the right time and at the right place. In the *E. coli* cell cycle the frequency of initiation of DNA replication equals Td. If $C + D < T_d$ newborn cells contain a replicating chromosome, which exemplifies the fact that a newborn cell is not completely new. The fastest division cycle in *E. coli* in rich medium at 37 °C is about 20 min, which is the same as the minimal D-period. Consequently, cells growing with a Td of 20 min are continuously involved in cell division. As outlined above such cells initiate DNA replication every 20 min, which makes multifork replication ($C > T_d$) a must. Cells have to 'know' when to initiate DNA replication and when to start cell division. As already indicated above this has to do, at least in part, with the accumulation of the Dna A protein.

Potential division sites (Figure 10) exist where there is no spatial obstruction by the nucleoid. This implies that the divisome is assembled after nucleoids have segregated upon completion of DNA replication. Thus, a regulating aspect seems to reside in the cells' perception of the location of its nucleoid, thus prohibiting the cutting of its DNA by the constricting envelope. This has become known as the nucleoid occlusion model. So far little is known about the sensing mechanism that links termination of DNA replication (and segregation) with initiation of division. However, recently DNA binding proteins (Noc and SlmA), which seem to interfere with divisome assembly have been detected in *B. subtilis* and *E. coli*, respectively. It is intriguing that cells are capable to adjust for DNA damage via the so-called SOS response, that is, cell division is postponed.

Progression of the cell cycle, as outlined above, is accompanied by segregation of replicating DNA, and the cellular redistribution of proteins involved in envelope synthesis. It includes the organized dynamic positioning of gene products in the growing cell. The combination of molecular genetics and fluorescence microscopy has contributed immensely to these insights. Yet, the underlying mechanism guiding growth of the individual cell remains to be elucidated.

Bacterial Chemotaxis: Conservation and Variation on a Theme[☆]

Elizabeth E Jefferys and Judith P Armitage, University of Oxford, Oxford, United Kingdom

© 2019 Elsevier Inc. All rights reserved.

Many bacterial species move through their environment. Their generally small size means they are unable to sense a gradient in space, but must sense it in time, comparing current conditions with those a few seconds ago. They then bias their random pattern of movement towards an improving environment (Fig. 1A). Remarkably, most species can respond to a change of around 1% in the concentration of a compound over a background of 5–7 orders of magnitude. This mechanism of responding to changes requires sensing, signal amplification, response, signal termination, and receptor adaptation, plus a memory of past concentrations. The advantages of being chemotactic are clearly seen in the simple experiments carried out by Julius Adler in the 1960s. *Escherichia coli* inoculated onto the middle on a soft, low-nutrient agar plate will metabolize the nutrients, creating a gradient, and then move down that gradient, filling the petri-dish with rings of growing cells after overnight incubation. However, if the cells are motile, but not chemotactic, they will spread a little as they randomly swim, but not be able to bias that movement towards an optimum environment. If non-motile, the colony will stay where it was inoculated with limited growth. Mutagenesis showed that the rings form as the colony spread down the concentration gradient because *E. coli* has four types of chemoreceptor, with each ring on the petri dish being a population of cells following a specific chemical gradient sensed by one of those receptors. Using transport mutants it was also shown that the chemoreceptors were not involved in either transport or metabolism, but connected to a dedicated sensory system. As we will discover later, it can be much more complex in other species.

Despite the different mechanisms used by bacteria to move: swimming, gliding, swarming, twitching in bacteria, and even the very different swimming of Archaea, all prokaryotes use a variation on the same histidine protein kinase system to control movement in response to chemical changes.

Core Components

E. coli is, of course, the best studied of all chemotaxis systems in bacteria and the core pathway identified in this species applies to most other species (Fig. 2A). Indeed it was fortuitous that this species was chosen by Julius Adler for chemosensory studies, as we now know that it has one of the simplest chemosensory systems, and therefore allowed the basic principles to be set in place in the 1960s and 70s. A decade earlier, Rod Clayton had investigated chemosensory responses in *Rhodospirillum rubrum* and despite heroic efforts and some exceptional papers, he changed fields after obtaining results which were really too complex to interpret in the days before molecular genetics and live cell imaging. *R. rubrum* chemosensing is exceptionally complex when compared with *E. coli*

- (a) **Chemoreceptors.** Bacteria must sense a change in concentration of a chemoeffector, usually a metabolite or a toxin. It was clear from early research that *E. coli* and its relative *Salmonella enterica* have different, but related, 55 kDa chemoreceptors named Methyl-accepting Chemotaxis Proteins (MCPs). Each of the four different MCPs (Tsr, primarily sensing serine and Tar sensing aspartate and maltose are high copy number while Trg sensing galactose and Tap, dipeptides are low copy number) of *E. coli* form transmembrane dimers, inserted into the cytoplasmic membrane and operating as trimers of dimers (Fig. 1B). Each monomer is a very long protein, around 30 nm, consisting of a periplasmic domain, which interacts with the chemoeffector, two transmembrane domains, and a long coiled-coil cytoplasmic domain. The periplasmic binding domain consist of a four-helix bundle with an effector-binding site on each. Depending on the MCP, the effector might be an amino acid or it could be a large sugar-binding periplasmic-binding-protein, with affinity for both the MCP and the transporter. Binding to one of the periplasmic monomer domains reduces the affinity for the site on the second monomer. In the case of Tar, binding of the attractant aspartate causes a small piston movement in the protein which is transmitted across the transmembrane domain. For other receptors, for example Tsr, binding of serine induces a helix-clutch mechanism to signal across the membrane. In each case these structural changes result in the same overall outcome, with a change in activity of the CheA kinase associated with the cytoplasmic tip of the MCP.

This change in structure in the transmembrane domains has to be communicated, through a long coiled-coil region over 20 nm long to the CheA kinase bound to the distant tip. Just below the membrane the MCPs contain a HAMP domain which is involved in transforming this transmembrane movement into that distant structural change. In *E. coli* each MCP monomer also has four conserved glutamate residues in the coiled-coil domain, two encoded as glutamines. These are the sites of adaptation (see later).

[☆]Change History: November 2018. Authors Elizabeth E. Jefferys and Judith P. Armitage updated all sections.

This article is an update of J.B. Stock, M.D. Baker, Chemotaxis, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 71–78.

Fig. 1 Shows the biased random walk of *E. coli* and *R. sphaeroides* and the organization of the chemosensory clusters and chemoreceptor structure. (A) *Top panel* shows the swim and tumble pattern of *E. coli* and the run and stop pattern of *R. sphaeroides*. Expanded cartoons show the arrangement of the chemosensory proteins in large membrane-associated and cytoplasmic clusters. Dark blue structures are chemoreceptors, red are CheA kinases and light blue CheW. Lower images are cryo-electron micrographs of the membrane and cytoplasmic clusters. (B) Shows the structure of an *E. coli* chemoreceptor dimer and (C) shows how homodimers forming two heterotrimers of dimers interacting with the CheA, shown as domains P1-P5, and CheW. These form large hexagonal arrays shown from the cytoplasmic side of cell. Dark blue circles are the dimers, orange and gray the CheA domains and light blue CheW.

Fig. 2 Shows the chemosensory pathways of (A) *E. coli*, (B) *R. sphaeroides*, and (C) *Bacillus subtilis*. Details of the pathways can be found in the text.

Chemoeffectors bind to specific sites between the periplasmic domains of the dimers and cause one of the monomers' transmembrane domain to move or twist. This movement is transmitted through the cytoplasmic domain to the tip. Analyses of isolated monomers, dimers and trimers of dimers in nanodiscs show that while signaling requires at least a dimer to activate the kinase, but two trimers of dimers are required for optimal signaling. While the dimers are homomeric, the trimers of dimers can be composed of different MCPs, even though their transmembrane signaling mechanism might be different. All four MCPs and the oxygen sensor Aer have identical contact residues at the receptor tip enabling interaction with the signaling proteins.

- (b) *Receptor networks.* Immunogold electron microscopy and fluorescent labelling of receptors and associated proteins showed that receptors tend to form large clusters, often in specific cellular sites, such as the poles or, late in the cell cycle, at midcell. Cryo-electron tomography revealed that these are not clusters of free trimers of dimers, but massive interconnected networks of hundreds to thousands of receptor trimers forming 12 nm hexagonal repeats connected by CheA and CheW proteins linking across trimers (Fig. 1C). It is thought that these massive protein complexes allow the sensitivity of the chemosensory system (see later).
- (c) *Signaling* two proteins are directly associated with the MCP tips: CheW, a small protein structurally very similar to the conserved tip domain, often called a linker protein as its precise role is unclear, and CheA, an unusual Histidine Protein Kinase (HPK). CheA is a soluble HPK which, unlike other HPKs, does not have an integral sensing domain, but instead responds to signals received by the associated MCPs, causing a two state transition between kinase-on and kinase-off. It has the conserved His site (P1) of an HPK separated from the ATP binding site (P4) by an additional, P2, domain. Two response regulator (RR) proteins compete for binding to the P2 domain. One, CheY, is a 15 kDa small, diffusible, single domain signaling protein and the other, CheB, has an adaptation methyl esterase enzyme domain linked to the RR domain. CheA functions as a homodimer. On the LOSS of an attractant, ATP binds to the Walker box on the P4 domain of CheA and a phosphoryl residue is transferred to the conserved His on the P1 domain of the partner monomer. The phosphoryl is then taken by the conserved Asp of one of the two RRs that might be bound to the P2 domain. Once phosphorylated the RR is released and, in the case of CheY~P diffuses to the flagellar motor where it binds to a FliM protein in the rotor C-ring to induce a switch in rotational direction of the motor and thus the cell to tumble. Calculations suggest that the binding or release of a single chemoeffector can alter the On-Off state of around 35 CheA kinases in the array and associated with the activated receptor, allowing for signal amplification. When CheB is phosphorylated its esterase activity is increased by up to 100-fold enabling it to remove methyl groups from the conserved glutamates on the MCPs and reset the signaling state of CheA and thus bring about adaptation.
- (d) *CheY signaling and signal termination.* CheY is one of the most studied RR proteins, as it is an easily crystallized, single domain RR protein. It has a classical RR fold, with five alpha helices surrounding a central five-stranded beta sheet, and an acidic pocket containing the phosphorylatable Asp. On phosphorylation of Asp37, the affinity for the P2 domain of CheA is decreased and the affinity for the FliM protein of the flagellar motor increased. Several hundred to thousand CheY~P molecules are therefore released from the chemosensory clusters and diffuse, in around 100 ms, to the motors. There are around 34 FliM proteins per motor and around six flagella per *E. coli*, depending on growth phase. The actual mechanism of switching rotational direction in a motor where the driving force (the ion motive force) is always inward remains unclear, but it is thought that CheY~P binding drives a cooperative change in the ring of FliM molecules and, after a threshold is reached, this conformational change is transferred to the rotor protein proper, FliG. The resulting alteration in charge interface with the ion transporting stator proteins induces a switch in rotational direction. The structural changes that occur in CheY when phosphorylated are also unclear, as CheY~P is unstable. Structural studies of the phosphorylated form rely on mimicking the phosphorylated state, either with beryllium fluoride or by mutations thought to lock the protein in the active conformation.

To be able to continue to respond to a changing environment, the signal must be terminated, that is, CheY~P must dephosphorylate. RRs do spontaneously dephosphorylate at a rate determined by the protein structure. Although CheY~P spontaneously dephosphorylates with a half time of about 14 s, that is too slow for bacterial chemotaxis. The size of bacteria means that in liquid they are constantly being buffeted by the environment and only swim smoothly for a few seconds. The CheY~P signal must therefore be “switched off” within a second or so. In *E. coli* this is achieved by a protein CheZ localized close to the sensory cluster, which binds CheY~P and accelerates the rate of dephosphorylation a 100-fold, switching off the tumbling signal. CheZ turns out to be confined to the gamma proteobacteria and other species have evolved very different mechanisms for rapid signal termination (see below).

- (e) *Adaptation* not only must the CheY~P signal be terminated, the chemoreceptors must also adapt, allowing the cell to sense and respond to future changes against a new background concentration. This is achieved by the addition and removal of methyl groups to the four conserved glutamate residues at specific sites on the long coiled-coil cytoplasmic domain of the MCPs. These sites are modified in any order and the extent of modification depends of the signal strength and the steady state background chemoeffector concentration. Given the thousands of receptors that might form part of a cluster, each with four adaptation sites, the number of adaptation states is extremely large. Adaptation was initially characterized when it was identified that methionine, and specifically S-adenosyl methionine (SAM), is required for adaptation. When tritiated SAM was added to *E. coli* and an attractant added or removed, four radiolabelled bands were seen on SDS PAGE gels at apparently different molecular weights. The weights increased by 1 kDa or so on addition of attractant and reduced on removal, reflecting the addition and removal of methyl groups to and from the glutamates. Each MCP has four conserved glutamate residues (Fig. 1B). Two are encoded as glutamines, ensuring that new MCPs are in a neutral signaling state when expressed and inserted into the membrane. The methyltransferase is also a specific deamidase, and deamidates the two glutamines, presumably after the MCPs are inserted into the membrane.

To allow adaptation to occur, CheB works in concert with a methyltransferase, CheR. This is constitutively active and tends to localize to a specific sequence at the C-terminus of the two most abundant MCPs; in *E. coli*, Tsr (a serine responsive receptor) and Tar (an aspartate and maltose receptor). The two low abundance receptors, Trg (ribose and galactose receptor) and Tap (dipeptide) lack the CheR binding domain but still have the conserved glutamates. The mixed trimers of dimers ensures a methyl transferase on the

high abundance receptors can interact with the low abundance receptor if it is activated. If an attractant binds, the activity of CheA is reduced, resulting in a reduction in CheB~P and therefore CheR can add methyl groups to exposed glutamates, neutralizing the charge. This serves to alter the cluster packing and to reset the structural state of the receptor and consequently the signaling state of CheA. Removal of the attractant, or addition of a repellent, causes CheA autophosphorylation and release of CheY~P and CheB~P. The esterase is now more active and removes methyls from the glutamates, releasing them as methanol, and resetting the signaling state of CheA and the receptor. The activation time of CheB and subsequent adaptation time is longer than the time taken to terminate the CheY~P signal, resulting in a memory of the recent change. In addition the sequential resetting of the responding receptors allows the cluster state to act as a memory of the past environment.

- (f) *Sensitivity, gain and adaptation* experiments measuring the responses to different signal strengths of mutants unable to adapt, but expressing single receptors locked into different methylation states revealed that the sensitivity range of the receptors is remarkable, with a Hill coefficient of over 11. Recently cryo-electron microscopy has shown structural changes in regions of the chemoreceptor array, suggesting that signaling and adaptation may occur within neighborhoods of receptors. This has led to a large number of papers developing models to explain this exceptional sensitivity of the bacterial chemosensory system.
- (g) *CheV*. *E. coli* and *S. enterica* encode homologous chemosensory pathways, except for one additional protein, CheV, found in *S. enterica*, but not *E. coli*. CheV resembles a CheW fused to a CheY-like RR domain and in some enteric species CheV is thought to act as an adaptor protein, linking chemoreceptors to CheA. It may have additional roles in other species as it is found in ~60% of genomes sequenced from motile species (see later). Genome analysis shows that species with few different chemoreceptors (on average five) tend to lack CheV, while those with more (on average 23) encode CheV. *S. enterica* has four more chemoreceptors than *E. coli*. This has led to the idea that CheV is a preferential adaptor allowing the clusters to accommodate certain chemoreceptors that cannot be accommodated into the cluster by CheW and exemplified by the *S. enterica* McpC chemoreceptor.

Numbers of Chemosensory Pathways and When is a Chemotaxis Pathway Not a Chemotaxis Pathway?

Given the conservation of the above core pathway over the many millions of years of evolution, it is unsurprising that different species have evolved modifications to this chemosensory pathway for survival in their own niches, some of which may be much more complex and varied than that of *E. coli*. There appears to have been both gene duplication and horizontal gene transfer, sometimes of whole pathways, tuning each species for its niche.

The advances in genome sequencing, combined with methods for looking at proteins within living cells has revealed that things are much more complex than the *E. coli* system in the majority of bacterial species. It was originally assumed that there were only four MCP types in *E. coli* because this conserved membrane usage and a change in just one or two amino acids or sugars probably reflected a more general changing environment. However, we now know that the majority of bacterial species have around 20 different chemoreceptors, with some having over 50. These are not only found in the membrane, but many species have both membrane spanning and soluble chemoreceptors, suggesting intracellular as well as periplasmic sensing. There are also chemoreceptors with different numbers of heptad repeats in the cytoplasmic coiled-coil domain, leading to different length cytoplasmic domains. Different length cytoplasmic domains might not readily form mixed trimers or dimers or pack into arrays, suggesting patches of receptors with different organizations.

Not only are there more chemoreceptors, presumably sensing a much wider range of chemoeffector than expected, but many species have multiple chemosensory pathways. Chemosensory pathways are identified from genome sequences by genes encoding receptors, CheY, CheA, and CheB and CheR, the latter almost always being encoded together. It now seems probable that not all pathways identified through genome sequence analysis actually encode chemosensory proteins. For example, *Pseudomonas aeruginosa* has three putative pathways, but one (Wsp) is certainly involved in EPS production and biofilm formation, and of the eight putative pathways identified in *Myxococcus xanthus* only three seem to control motile behaviour. The pathway Che1 controls chemosensory reversals of single cells of this gliding bacterium using a mechanism similar to *E. coli* chemotaxis, but employing soluble chemoreceptors, while Che4 and Che7 appear to be involved in social motility and fruiting body development, respectively.

Rhodobacter sphaeroides encodes three putative pathways and there is evidence that all of these are involved in motility. *R. sphaeroides* has two different flagellar systems. Analysis suggests one flagellar system, forming polar tufts, was the original flagellar system controlled by one of the chemotaxis pathways (CheOp1), but neither this flagellar system nor its chemotaxis pathway are expressed under normal laboratory conditions. The other two pathways control the other single, randomly positioned flagellum. One pathway localizes to the cell poles with transmembrane chemoreceptors, as seen in *E. coli*, while the other localizes to midcell (in a newly divided cell) with a cluster of soluble chemoreceptors. The CheA associated with the cytoplasmic cluster is split into two proteins, with the kinase domain (CheA4) separate from the P1 histidine domain (CheA3). CheA3 controls the phosphorylation state of the dominant CheY, CheY6, through phosphorylation via CheA4 and dephosphorylation through a domain of CheA3. CheA3 and CheA4 have different P5 receptor-binding domains, suggesting different input signals. This would allow phosphorylation via CheA4 to P1 of CheA3 and dephosphorylation via the phosphatase domain to be independently controlled, and to tune the level of CheY6~P in the cell in response to metabolic signals. It seems probable that the dominant chemosensory pathway is the cytoplasmic pathway, controlling a background level of CheY6~P, and only if the level is below a threshold do the CheY3~P or CheY4~P proteins released from the membrane chemoreceptors in response to extracellular stimuli cause a change in behaviour.

By tuning the level of the motor-stopping $\text{CheY} \sim \text{P}$ to the metabolic state, the strength of the response to changes in the external conditions will depend on the metabolic needs of the cell (Fig. 2B). Interestingly, *R. sphaeroides* only responds to the removal of chemoeffector, not their addition.

Different Methods of Termination and Adaptation

It is clear that the $\text{CheY} \sim \text{P}$ signal needs to be terminated, but CheZ is only found in the gamma proteobacteria. Other groups have different termination mechanisms. *R. sphaeroides* has a large internal domain, between the CheA3P1 and P5 domains, that acts as a specific phosphatase for $\text{CheY6} \sim \text{P}$, but not $\text{CheY3} \sim \text{P}$ or $\text{CheY4} \sim \text{P}$. $\text{CheY3} \sim \text{P}$ and $\text{CheY4} \sim \text{P}$ may themselves use a different mechanism to terminate. In many related alpha proteobacteria, one CheY acts as a phosphate sink. In *Rhizobium meliloti*, one CheY is phosphorylated and can bind the motor, but can also transfer phosphoryl groups back to the CheA, and the second CheY, which does not bind the motor, spontaneously dephosphorylates, acting as a phosphate sink. The flux of phosphoryls thus regulates signal strength and rate of termination.

Similarly, while adaptation is a key component essential for chemotaxis, and most species encode CheB and CheR, almost always in the same operon, most do not have a CheR-binding domain in the MCPs. Although the adaptation glutamates in *E. coli* are readily identifiable from their positions relative to each other on the receptors, they are harder to identify in other species. Glutamates suggested to be involved in adaptation on the cytoplasmic chemoreceptor TlpT of *R. sphaeroides* using bioinformatic methods proved to not be involved, but mass spectroscopy of peptides isolated from receptors stimulated in backgrounds lacking either CheR3 or CheB2 identified four methylatable glutamates in different positions on the receptors to those of *E. coli* MCPs. As with *B. subtilis*, mutating these sites produced populations which did not adapt, but with each site producing a different swimming phenotype when mutated (unpublished results, this lab).

Variation in Signaling

Bacillus subtilis has many of the same chemosensory proteins as *E. coli*, but has a number of additional proteins, and many of the signaling mechanisms are the reverse of those of *E. coli*. *B. subtilis* has a CheA and a CheY, but in this case the addition of an attractant activates the kinase and increases $\text{CheY} \sim \text{P}$ levels resulting in continued smooth motor rotation, rather than motor reversals (Fig. 2C).

Adaptation is also more complex. Unlike *E. coli*, where methylation/demethylation of the MCP glutamates does not occur in any specific order, in *B. subtilis* the methylation sites are regulated and the methylation of specific glutamates has different effects on behaviour. For example, methylation of an MCP at position 371 will activate the kinase, while methylation of the glutamate at position 630 will inhibit the kinase, suggesting much more complex structural changes in different regions within the receptor cluster causing different kinase outputs. In addition to receptor methylation, *B. subtilis* has two other adaptation systems, CheC/CheD/ $\text{CheY} \sim \text{P}$ and CheV. CheD tunes kinase activity relative to the adaptation state of the receptor while the activity of CheV depends on whether or not position 630 is methylated, allowing this species to very finely tune its behaviour to current conditions.

Conservation of Cluster Geometry and Role in Signaling

One of the surprising recent discoveries is that the cytoplasmic clusters found in species as diverse as *R. sphaeroides* and *Vibrio cholerae* are arranged in exactly the same pattern as each other and the cytoplasmic receptors and kinases are arranged in the same hexagonal arrangement as that seen in the membrane chemoreceptor clusters. The major difference is that the cytoplasmic receptor arrangement is organized as a sandwich of receptors with the equivalent of the MCP periplasmic domains overlapping slightly in the middle of the sandwich. The CheW and CheA kinases then form on the outer surface of the sandwich (Fig. 1). This suggests that for chemosensory signaling, sensitivity and gain, the array provides the optimum, critical geometric arrangement.

Positioning of Clusters

It was originally thought that the receptor clusters of *E. coli* were at the poles to allow the lateral membrane to be used for other functions. This now seems unlikely, given the numbers of receptors and sizes of the clusters. The clusters may form by diffusion-capture: as new receptors are inserted into the membrane they diffuse and either are "captured" by a forming cluster or, if too far, nucleate their own cluster. They may end up at the poles because the shape of the trimer of dimers slows diffusion from the more highly curved poles. This is certainly the case for the membrane clusters of *R. sphaeroides* where clusters of 800 or so receptors diffuse freely in sphaeroplasts, but are mainly at the poles of normal cells.

The positioning of the cytoplasmic clusters is more complex. The receptors of polarly flagellate species such as *V. cholerae* and *V. parahaemolyticus* are actively positioned through a protein targeted to the cell pole, HupP. This protein, which may anchor to the peptidoglycan, recruits ParA-like ATPases, required to recruit the *OriC* of the major chromosome, the polar flagellum and the CheII

chemotaxis proteins controlling flagellar activity. In the case of the Che cluster the ATPase is ParC, which forms a cluster at the flagellate pole, recruiting ParP, which has a CheW domain and interacts with CheA, helping form a complete chemosensory cluster. Similar systems may operate in species such as *Shewanella*.

In *M. xanthus* the cytoplasmic FrzCD chemoreceptors (Che1) localize as multiple clusters along the nucleoid, interacting directly with the nucleoid through their N-termini and probably being stochastically positioned. The FrzCD chemoreceptors recruit the partner chemotaxis proteins to form the functional cluster arrays. It is thought that nucleoid-dependent formation of multiple clusters ensures inheritance of functioning chemotaxis systems on division. In the much smaller *R. sphaeroides* there is only one cytoplasmic cluster after division. As the cell grows this cluster splits and one part moves to each of the daughter cells. Without a ParA-like protein, PpfA, the cluster forms, but is not associated with the nucleoid, does not divide and only one daughter inherits a cluster. PpfA localizes to the nucleoid surface and interacts with the N-terminal domain of TlpT, the dominant cytoplasmic chemoreceptor. TlpT is required for the formation of a chemosensory cluster, but requires PpfA to piggy-back on the chromosome surface and divide and segregate as the cell grows and divides. Unlike plasmid inheritance, which uses a related system, the process for segregating the chemosensory cluster using chromosome segregation appears passive rather than active. TlpT binds PpfA and nucleates a chemosensory cluster. The cluster splits when the chromosome divides with one cluster going with each chromosome. There are no specific binding domains and PpfA does not seem to actively move the cluster.

Interactions With Other Pathways

Chemotaxis does not operate in isolation of other sensing systems or the growth state of the cell. Although membrane spanning chemoreceptors do not transport chemoeffectors and the chemoeffectors do not need to be metabolized, it seems that the strength of the response to different amino acids by *E. coli* does depend on its suitability as a nutrient. However *B. subtilis* responds equally to all amino acids, suggesting they simply reflect an increase or decrease in overall nutrient levels.

Oxygen levels in the atmosphere have obviously changed greatly during the evolution of bacteria. Reflecting the very different lifestyles of different species, a wide range of mechanisms for sensing oxygen have evolved, from cytoplasmic haem-containing receptors in the strictly anaerobic *Desulfovibrio* to the well-studied FAD Aer receptor in *E. coli*. In *E. coli*, Aer is a membrane anchored protein with a PAS domain and a bound FAD below the membrane followed by the conserved coiled-coil of an MCP, but without adaptation sites. The redox state of FAD changes with the rate of electron transfer through the respiratory electron transport chain, which alters the redox state of the quinones. This feeds through to CheA and regulates the activity of CheY. In the soil alpha proteobacterium *Azospirillum*, which prefers a microaerophilic environment, the response to oxygen is closely linked to cyclic di-GMP levels. Cyclic di-GMP is a molecule identified across a wide range of species as regulating the switch between a free living state and biofilm formation. In *Azospirillum brasilense*, *c*-di-GMP binds to the oxygen chemoreceptor, Tlp1, and tunes the strength of the response to oxygen. As the intracellular levels of *c*-di-GMP change with the level of available carbon, this directly links the response to oxygen to the current metabolic state of the cell.

Oxygen sensing also influences the behaviour of magnetotactic bacteria. Many species of bacteria show responses to the Earth's magnetic field. They are able to synthesis intracellular magnetite, which is organized into magnetosomes along the length of the cell body, giving the cells a magnetic dipole. The majority of identified species are microaerophiles living in estuarine mud and show negative aerotaxis. It is thought that the magnetosomes orient the bacteria along the Earth's field lines then negative aerotaxis rapidly returns the bacteria to an optimum oxygen level. In *Magnetospirillum gryphiswaldense*, the magnetotactic direction of swimming polarity can be changed by a change in oxygen gradient sensed through one of its four chemosensory operons (CheOp1), suggesting a direct link between aerotaxis and magnetotaxis.

While most investigations into *E. coli* behaviour have concentrated on the MCPs, which only require binding to the periplasmic domain of the chemoreceptor, it has been known for many decades that *E. coli* also responds to PTS sugars, and the response is dependent on transport. PTS sugars are transported through specific transporters via a PEP-dependent transport system. PEP transfers a phosphoryl to an EI protein which, through a common HPr protein, phosphorylates an EII protein responsible for phosphorylating the specific sugar. Transport therefore directly affects the phosphate pools in the cell. EI and EII can directly interact with CheA and CheW to affect the signaling state of CheA. Thus, as the sugar levels increase, the activity of CheA decreases and the length of smooth swimming increases.

The serine receptor, Tsr, of *E. coli* not only responds to serine levels, but can respond to the autoinducer AI-2. This quorum sensing molecule is involved in biofilm formation in a range of species, where it diffuses freely through the cell membrane. When the population reaches a critical threshold, the level of intracellular AI-2 is high enough to activate transcription of a range of specific pathways. In *E. coli* it also binds Tsr and on binding it promotes autoaggregation. Similar effects have been seen in *A. brasilense* although in both cases the connection between autoaggregation, chemotaxis and biofilm formation is unclear.

Conclusion

The similarity between the core components of the chemosensory pathways identified across bacterial, and archaeal, species suggests an ancient ancestry. The additional complexities of some pathways reflect the duplication and adaptation of the individual pathways to the niches of those species. All pathways studied to date have diffusible CheYs being released from large hexagonal

arrays of chemoreceptors and binding to the cytoplasmic face of the motor to control its activity. The signals are terminated and the receptors adapt, resetting the signaling state of the kinase. These feedback systems, with signaling, termination and receptor adaptation occurring through large dynamic interactive sensory arrays allow bacteria to show exquisite sensitivity to changes in their background, with most able to respond to ~1% changes in concentration over 5–7 orders of magnitude, and enable motile bacteria to reach or maintain themselves in their optimum environment for growth.

Bacterial Development

Introduction

All developmental model organisms perform some complicated, multi-step activity that goes above and beyond the normal growth and division performed by all bacteria. These developmental systems integrate multiple individual processes into a larger complex physiological scheme. Therefore, the challenge in understanding bacterial development is one of understanding how all the moving parts of a machine work in concert to accomplish a given task. As development involves the coordination of multiple processes, signaling systems and regulatory networks figure prominently in developmental models. In fact, coordination is a key principle in bacterial development. It is not enough simply for a process to occur, it must occur at the right time and at the right place. Whether it's the subcellular protein localization and temporal progression of global regulators in *Caulobacter crescentus*, the communication between subcellular compartments during endospore formation in *Bacillus subtilis*, or the multi-day accumulation and organization of *Myxococcus xanthus* cells into a fruiting body, all the model developmental bacteria require precise spatial and temporal control of activities. In this article, some of the major model developmental organisms will be presented, and examples of regulatory systems used to coordinate activities in each model will be highlighted. It is worth noting that the regulatory pathways presented here are often simplified versions, and many intricate details are abridged for the sake of simplicity. The reader is encouraged to seek out more specific literature on a given topic to truly appreciate the subtle nuances of these systems.

Cellular Asymmetry and the Dimorphic Life Cycle of *Caulobacter crescentus*

Caulobacter crescentus is a freshwater aquatic microbe of the Alphaproteobacteria, and is a model developmental bacterium because of its unusual dimorphic life cycle. Instead of producing two identical cells after binary fission, *C. crescentus* produces two cells that differ in both their morphology as well as their replication capability (Fig. 1). The cell cycle begins with a stalked cell, a crescent shaped cell with a thin extension of the cell body from one pole called a "stalk". The stalk is tipped with an adhesive polysaccharide termed the "holdfast". As the stalked cell grows in size and prepares for division, it is termed a "predivisional cell". During the predivisional cell stage, a single flagellum is synthesized at the pole opposite the stalk, though it is held in an inactive state. Once cell division occurs, flagellum rotation is activated and pili are produced at the same pole as the flagellum. The asymmetric positioning of cell structures (stalk vs. flagellum/pili) is critical to the developmental program of *C. crescentus*, as the two progeny cells inherit different structures and are therefore different cell types. One cell inherits the stalk and holdfast, is non-motile, and is the same as the progenitor stalked cell; the other cell inherits the flagellum and pili and is a motile "swarmer cell". The cell types are also different in their reproductive capability. The progeny stalked cell is able to immediately enter the replication cycle, however the progeny swarmer cell cannot replicate and must spend a portion of its life cycle swimming. Eventually, either as a function of time or due to contacting a surface, the swarmer cell differentiates into a stalked cell. It does so by ejecting the flagellum, retracting the pili, and producing a stalk and holdfast from the same pole. Only when it has differentiated into a stalked cell is that cell able to replicate and divide. *C. crescentus* typically inhabits oligotrophic (i.e., very low nutrient) environments and it is thought that the swarmer cell stage is an obligate dispersal stage, forcing *C. crescentus* to constantly seek new environments to colonize.

Progression through the predivisional stage is tightly controlled by a sequential series of global transcriptional regulators, each regulator controlling the expression of dozens of genes, and is intertwined with the progression of chromosome replication. Chromosome replication is initiated by DnaA which also serves as a global regulator. One of the regulatory targets of DnaA is another global regulator GcrA. A regulatory target of GcrA is CtrA, a third global transcriptional regulator. CtrA is perhaps the most important regulator in *C. crescentus* development, regulating over 100 genes, including those involved in the flagellum biosynthesis cascade, pilus synthesis genes, chemotaxis genes, and cell division genes. CtrA also binds to five places in the origin of replication and prevents chromosome replication. Not only does the activity of one regulator lead to the activity of the next, each regulator also faces checkpoints from other physiological activities to ensure that it does not become active before a critical step has become accomplished. An example of this is in the regulation of CtrA by GcrA.

GcrA is an unusual DNA binding protein whose activity is, at least in part, regulated by the methylation state of the chromosome. At the beginning of the cell cycle, the chromosome is fully methylated on both strands, but the methyltransferase CcrM is not active. Newly synthesized DNA strands are unmethylated, so two hemimethylated chromosomes are produced during replication (where the old strand is methylated and the new strand is not). GcrA induces CtrA production by binding to the first of two promoters (P1) of the *ctrA* gene, but GcrA is unable to activate transcription from this promoter while the chromosome is fully methylated. Only once the replication fork has passed through this region and the *ctrA* promoter becomes hemimethylated is GcrA able to induce transcription from this promoter. Thus the expression of CtrA is tied not only to GcrA activity, but to successful chromosome replication as well. The use of chromosome replication as a timing and quality control measure requires an unusual feature of

Fig. 1 Diagram of the *C. crescentus* cell cycle. The cycle begins with a stalked cell (ST). The stalk is tipped with an adhesive polysaccharide called the holdfast (HF). As the cell grows larger in preparation for cell division, it is called a predivisional cell (PD). During this stage, a flagellum (F) is made on the pole opposite the stalk. At the time of cell division, flagellum rotation is activated. The daughter stalked cell is able to re-enter the replication cycle. The other daughter cell inherits the flagellum and is motile, so is called a swarmer cell (SW). At this time pili (P) are also extended at the flagellar pole. The swarmer cell is unable to replicate until it differentiates into a stalked cell by ejecting the flagellum, retracting pili, and synthesizing a stalk and holdfast at that pole.

C. crescentus in that chromosome replication is initiated once and only once each cell cycle. Most bacteria, when rapidly growing in exponential phase, will initiate a round of chromosome replication before the previous round is finished, which sometimes lead to multiple chromosomes in different stages of replication completion.

The critical activity of CtrA is not just controlled by the timing of its expression. CtrA is also spatially controlled such that its activity is maintained in the swarmer cell but not the stalked cell. This spatial control prevents chromosome replication in the swarmer cell while permitting it in the stalked cell. CtrA is a response regulator and is activated by a phosphorelay beginning with the hybrid histidine kinase CckA and using the histidine phosphotransfer protein ChpT. Activation of CtrA in the swarmer cell and not the stalked cell is accomplished by specific activation of CckA in the swarmer cell. This spatial activation of CckA is accomplished by a very unusual signaling network composed of several other two-component signaling proteins (Fig. 2). The two component histidine kinase protein DivJ is localized to the stalked pole of the predivisional cell. Unlike most histidine kinases, DivJ does not recognize a specific signal but instead constitutively phosphorylates its target response regulator DivK. At the flagellar pole of the predivisional cell is the histidine kinase protein PleC that also does not recognize a signal but in this case constitutively dephosphorylates DivK (many histidine kinases can switch between kinase and phosphatase activities depending on the circumstances). How each protein becomes targeted to its specific pole is not well understood. This spatial arrangement means that after cell division, the progeny stalked cell inherits DivJ activity resulting in all DivK in that cell becoming phosphorylated. Conversely, the progeny swarmer cell inherits PleC resulting in all its DivK becoming dephosphorylated. It is the phosphorylation state of DivK in the newly born cells that ultimately controls CtrA activity in those cells as described below.

The hybrid histidine kinase CckA does not respond to a chemical signal. Instead, its activity is regulated through interaction with a histidine kinase DivL. DivL is unusual in that instead of a histidine that accepts phosphoryl groups, it has a tyrosine and most likely does not participate in phosphotransfer. Instead, it interacts with CckA, promoting kinase activity of that protein. When DivK is phosphorylated, such as in the progeny stalked cell, it disrupts functional DivL-CckA interaction and actually causes CckA to switch to phosphatase activity, reversing phosphate flow through the pathway, causing CtrA to become dephosphorylated and inactive, ultimately relieving repression of the origin of replication and allowing chromosome replication to initiate. In the progeny swarmer cell, DivK is non-phosphorylated, DivL-CckA interaction is not disrupted, phosphate flows toward CtrA and thus its activity is maintained, preventing chromosome replication initiation. It is this amazing

Fig. 2 Spatial control of CtrA regulation in *C. crescentus*. (A) In the predivisional cell, stalked-pole-localized DivJ phosphorylates DivK while flagellar-pole-localized PleC dephosphorylates DivK. (B) After cell division, in the stalked cell DivK becomes phosphorylated and disrupts a functional interaction between DivL and CckA, which reverses phosphate flow through the CckA-ChpT-CtrA/CpdR pathway, leading to CtrA dephosphorylation (deactivation) and proteolysis induced by dephosphorylation of CpdR. In the swarmer cell, DivK becomes dephosphorylated, permitting functional interaction between DivL and CckA, inducing phosphate flow through the CckA-ChpT-CtrA/CpdR pathway, leading to CtrA activation and protein stability by deactivation of CpdR by phosphorylation. Spatial control of CtrA leads to the stalked cell being able to replicate the chromosome while the swarmer cell cannot. In this diagram, histidine kinases are red, response regulators are blue, the Hpt protein ChpT is green, and the unusual histidine kinase DivL is yellow.

combination and integration of signaling proteins that leads to asymmetric activation of the master regulator between two progeny cells. CtrA is so important to cellular function that *C. crescentus* has redundant mechanisms to ensure its appropriate activity/inactivity. While ChpT can pass phosphates to CtrA to activate it, ChpT can also pass phosphates to a single domain response regulator CpdR. CpdR controls the stability of the CtrA protein by targeting it for proteolysis by the housekeeping ClpXP protease. When CckA is in the kinase state, CtrA is phosphorylated and active while CpdR is phosphorylated and inactive, leading to CtrA protein stability. When CckA is in the phosphatase state, CtrA is dephosphorylated and inactive and CpdR is dephosphorylated and active, targeting CtrA for degradation. Thus when CtrA is active, it is stabilized, but when it is dephosphorylated the protein itself is also removed from the cell, ensuring there is no residual CtrA activity. CtrA is a prime example of the massive amounts of regulation and coordination involved in performing developmental processes.

Endospore Formation of *Bacillus subtilis*

Bacillus subtilis is a Gram positive member of the Firmicutes phylum and best known for the ability to produce stress-resistant, metabolically-quiescent spores that can remain dormant but viable for many, many years. These spores are formed inside the cell and thus are referred to as “endospores”. Spores are produced in response to starvation, but the process of sporulation is costly in

Fig. 3 Regulation of events during *B. subtilis* starvation. Starvation signals induce signaling through five histidine kinases (KinA-E), inducing phosphate flow through the Spo0F-Spo0B-Spo0A phosphorelay. Spo0A (gray box): Spo0A-P levels increase over time. Competence (green box): Vegetatively produced ComX quorum signaling peptide, if accumulating to sufficient levels, induces signaling through the ComP-ComA two-component system. ComA-P induces expression of ComK, which positively regulates itself. ComK production leads to expression of competence genes. Both ComA-P and ComK lead to production of Rap phosphatases which dephosphorylate the main phosphorelay, preventing Spo0A phosphorylation. Each Rap phosphatase has a cognate Phr quorum peptide that is expressed and exported. If these accumulate to sufficient levels they inhibit Rap phosphatase activity, permitting phosphate flow through the phosphorelay. Biofilm (orange box): Low levels of Spo0A-P induce expression of SinI, an inhibitor of SinR, which itself inhibits biofilm formation. Therefore, low levels of Spo0A-P induce biofilm formation. Cannibalism (blue box): Low levels of Spo0A-P induce production of *skf* and *sdp* gene products, which include toxins and associated resistance proteins that induce lysis of other cells, including neighboring *B. subtilis*. Released cellular contents can be utilized for nutrients. Sporulation (yellow box): Only if starvation conditions persist long enough for Spo0A-P to reach high levels is sporulation finally induced.

both time and energy. Additionally, while the spore itself is viable, the cell that produces the spore is killed in the process. Therefore, the decision to sporulate is a very important one, and *B. subtilis* has multiple responses to starvation prior to initiating sporulation that are all integrated in a signaling network (Fig. 3). The backbone of this signaling network is composed of the phosphorelay proteins Spo0F, Spo0B, and the master regulator Spo0A. Phosphorylation through this pathway is initiated by any one of five histidine kinases (KinA-E). While kinase activity is stimulated by starvation signals, for the most part the exact nature of the signal for each kinase is not well understood. Once kinase activity is induced, phosphates are passed along the relay to the terminal response regulator Spo0A, which induces sporulation when phosphorylated. However, there are many processes that can occur before sporulation is ultimately initiated.

One process that can occur before sporulation is competence, whereby the *B. subtilis* cell can take up and assimilate foreign DNA from the surrounding environment. During vegetative growth (i.e., when cells are actively growing), *B. subtilis* cells produce the quorum signaling peptide ComX which can build up in the extracellular environment to sufficient levels to activate its target receptor, the histidine kinase ComP. ComP then phosphorylates the response regulator ComA, which is then able to induce production of the transcriptional regulator ComK. ComK stimulates its own expression, leading to a positive feedback loop and a burst of ComK production, which induces expression of the competence genes. In addition, both ComA~P and ComK induce expression of a number of phosphatases (including RapA, RapB, and RapH) that remove phosphates from the Spo0F-Spo0B-Spo0A pathway. Therefore, while competence is active, sporulation cannot occur. Presumably this is because the uptake of foreign DNA may provide proteins that can open up a previously untapped nutrient source and relieve the starvation. However, competence does not provide a permanent blockage to sporulation. When Rap phosphatases are produced, corresponding quorum signaling Phr pheromone peptides are also produced and excreted. Once these peptides build up to sufficient levels, they re-enter the cell and inhibit their cognate phosphatase either directly or indirectly.

Once Rap phosphatase inhibition has been relieved, Spo0A~P levels begin to rise. Yet again, there are still more processes that can occur before sporulation. Low Spo0A~P levels induce the production of SinI, an antagonist of the protein SinR, which itself inhibits biofilm formation. Thus low Spo0A~P levels induce biofilm formation, which can provide many physiological advantages to a starving cell. Low Spo0A~P levels also induce expression of *skf* (sporulation killing factor) and *sdp* (sporulation delaying

Fig. 4 Developmental progression of *B. subtilis* spore formation. Once the vegetative cell enters sporulation, the chromosome is duplicated and both copies are condensed to axial filaments along the horizontal length of the cell. Asymmetric septation occurs across one chromosome, making the larger mother cell compartment and smaller forespore compartment. The remainder of the chromosome is translocated into the forespore compartment. Degradation of the peptidoglycan septum allows the mother cell to engulf the forespore, giving the spore two membrane bilayers. A thick peptidoglycan cortex is assembled between the bilayers and a complex spore coat is assembled on the exterior of the spore by the mother cell. The spore core undergoes changes to protect the chromosome. The mother cell lyses to release the spore, which can germinate under favorable conditions to become a vegetative cell.

protein) genes. Some of the products of these genes are secreted toxins that kill and lyse neighboring *B. subtilis* cells. The components of the lysed cells provide nutrients and resources to the toxin-producing cells; this process is referred to as “cannibalism” and serves to (at least temporarily) relieve starvation. Thus, competence, biofilm formation, and cannibalism all can occur as starvation responses prior to sporulation, and only if these processes fail to relieve starvation and Spo0A~P rises to high levels is sporulation finally induced.

The process of sporulation begins with the replication of the host chromosome such that there are two copies (Fig. 4). The chromosomes are then condensed along the long axis of the cell as a linear “axial filament”. A septum is produced at an asymmetric point of the cell. The placement of the septum is the first committed step of sporulation; after this point, sporulation will complete even if nutrients are introduced to the cell. Septation causes the formation of two cellular compartments: the larger mother cell compartment and the smaller forespore compartment. Septation also temporarily traps a portion of one chromosome in the forespore compartment. At this point, the two compartments begin to have different patterns of gene expression. After a time, the remainder of the trapped chromosome is translocated into the forespore compartment by the DNA pump SpoIIIE, the septum is completed, and the septum peptidoglycan is degraded, bringing the mother cell and forespore membranes into direct contact. Further peptidoglycan degradation is coupled to a ratchet system that leads to the mother cell engulfing the forespore, thereby giving the forespore a second membrane. A thick peptidoglycan layer called the “cortex” is produced between the membranes. The core of the spore undergoes several changes, including protection of the DNA by small acid-soluble proteins and dehydration. Additionally, over 80 different proteins are produced and assembled by the mother cell onto the forespore, creating the inner and outer layers of the spore coat. It is the combination of spore core, cortex, and coat that give the *B. subtilis* spore its amazing stress resistance properties. Sporulation ends when the mother cell lyses and releases the mature spore.

During sporulation, each compartment has a progression of alternative sigma factors that drive expression of their own regulons and the distinct patterns of gene expression. High levels of Spo0A~P lead to the production of two sigma factors: σ^E and σ^F ; however, both sigma factors are held in an inactive state. σ^E is in a proteolytically unprocessed and inactive form (pro- σ^E), and σ^F is sequestered by the anti-sigma factor SpoIIAB. Both sigma factors are produced prior to septation and thus are found in both compartments once septation occurs. However, septation leads to compartment specific activation. SpoIIAA is an anti-anti-sigma factor that binds the anti-sigma factor SpoIIAB, but is prevented from doing so by a covalently attached phosphate group. Septation leads to activation of the SpoIIIE phosphatase in the forespore compartment, which removes the phosphate from SpoIIAA. SpoIIAA then binds to SpoIIAB, thus releasing σ^F and allowing it to initiate transcription from σ^F -dependent promoters. Therefore, σ^F only becomes active in the forespore compartment. One of the regulatory targets for σ^F is the gene encoding SpoIIR, a protein that enters the inter-compartmental space and activates the membrane-bound SpoIIGA protease in the mother cell membrane, which processes pro- σ^E into the active σ^E . Therefore, activation of σ^F in the forespore leads to activation of σ^E in the mother cell. Another regulatory target of σ^F is the gene encoding σ^G . σ^G is inactive until engulfment of the forespore occurs, but the mechanism of activation is unclear. Activation of σ^G requires the expression of the *spoIIAA-AH* operon driven by σ^E in the mother cell. These proteins have similarity to Type III secretion complexes and it is thought that they form a channel from the mother cell to the interior of the engulfed spore (the “feeding tube hypothesis”). What is unknown is how exactly this channel leads to σ^G activation. One theory is that the nascent spore is metabolically diminished because nutrients have no way to enter that compartment, and σ^G -dependent transcription occurs once the feeding tube provides energy to that compartment. Alternatively, activation of σ^G seems to strongly depend on SpoIIAG and SpoIIAH, so it is possible that the feeding tube provides a mechanism for these proteins to reach into the

forespore compartment and relieve some type of specific inhibition on σ^G . Regardless, both engulfment and σ^E activity are necessary for proper σ^G activity.

Another regulatory target of σ^E is the gene encoding σ^K , which, like σ^E , is produced as an inactive pro-protein. Activation of σ^G in the forespore leads to expression of the forespore protein SpoIVB, which leads to activation of the mother cell protease SpoIVFB, which processes pro- σ^K into the active σ^K form. In total, each compartment has its own sigma cascade, with σ^F to σ^G in the forespore, and σ^E to σ^K in the mother cell. Each cascade functions in parallel, but there is extensive cross-compartment communication and checkpoint control to ensure that the next stage in the process only occurs once a previous stage was successful. As seen here and in the *C. crescentus* system as well, checkpoints are vital to coordinating multiple processes.

***Myxococcus xanthus* Fruiting Body Formation**

A member of the Deltaproteobacteria, *Myxococcus xanthus* is most commonly found in soil. That is because *M. xanthus* is a predatory microbe and prefers to be in environments with the highest prey density. *M. xanthus* secretes hydrolytic enzymes that degrade prey cells and then metabolizes the contents. However, the effectiveness of a single cell secreting these enzymes is limited, so *M. xanthus* travels in multicellular swarms, thereby pooling the hydrolytic enzymes from multiple cells to increase feeding efficiency. This has caused *M. xanthus* to be referred to as “wolf pack predators”. When a swarm of *M. xanthus* is starved, the cells aggregate together to form a 3-dimensional, spore-filled structure called a “fruiting body”. It is thought that the fruiting body serves to keep the spores together so that when they germinate they are able to immediately re-establish a swarm. Fruiting body formation is a potent example of cellular differentiation because different cells have different destinies during the process (Fig. 5). Only one in ten cells actually becomes a spore inside the fruiting body. Most cells die and are cannibalized for energy during the process, which can take days to complete. Some cells never enter the fruiting body but instead stay outside as “peripheral rods”, potentially acting as guards to prevent other bacteria from invading the fruiting body.

Fruiting body formation is a concert of cellular organization which requires constant intercellular communication, where the end result is a careful arrangement of cells into a structure with varying levels of spatial intricacy. While the *M. xanthus* fruiting body is a relatively simple mound shape, other Myxobacteria form more elaborate fruiting body structures. Regardless of the exact

Fig. 5 Cell types and forms of *M. xanthus*. (A) a single vegetative cell (bar=1 μ m). (B) a myxospore (bar=1 μ m). (C) cells aggregating into fruiting bodies (bar=20 μ m). (D) a *M. xanthus* fruiting body (bar=20 μ m). From Shimkets, L.J., 1999. Intercellular signaling during fruiting-body development of *Myxococcus xanthus*. Annu. Rev. Microbiol. 53, 525–549. Copyright 2006 Annual Reviews.

organization, intercellular communication is a key aspect of the process. Much of the research into fruiting body formation has been driven by the examination of extracellular complementation groups. These are groups of mutants that are unable to form fruiting bodies on their own but can form fruiting bodies when mixed with wild-type cells or mutants from another group. Presumably this complementation is performed by some extracellular signal. Five major complementation groups have been characterized (A, B, C, D, and E signaling mutants), and the mechanisms behind these phenotypes are understood to greater or lesser extent. The A and C signals are the most well-characterized and will be presented here. The A signal is one of the earlier signals during fruiting body formation. *M. xanthus* responds to starvation much like other bacteria by producing the alarmone ppGpp, synthesized by the RelA enzyme when tRNAs uncharged with their respective amino acid enter the ribosome (known as the “Stringent Response”). The buildup of ppGpp somehow induces signaling through the unusual two component signaling protein ApgA, which is a hybrid histidine kinase with an N-terminal response regulator receiver domain. Signaling through this protein leads to production and export of protease enzymes, which degrade extracellular proteins and thus release small peptides and amino acids. While it may seem like this response serves to produce more nutrients in response to starvation (and it may do so to a certain extent), this mixture of amino acids actually serves as the extracellular A signal and functions as a quorum sensing system. The mixture of amino acids builds up over time and leads to the next stage of fruiting body formation by inducing signaling through the SasS/R two component system. An interesting facet of the A signal is that the signal is not a specific molecule, but instead a mixture of amino acids with Tyr, Pro, Phe, Trp, Leu, and Ile amino acids having more stimulatory activity.

A signaling occurs ~2 h after starvation, while the next signal (C signal) occurs ~6 h after starvation. C signaling is driven by the protein CsgA which has homology to short chain alcohol dehydrogenase enzymes. The molecular mechanism for C signaling has been extensively studied and is the subject of some controversy. Some evidence suggests that the enzymatic activity of CsgA is critical, as fruiting body formation in *csgA* mutants can be restored by over-expressing a different short chain alcohol dehydrogenase SocA. Other evidence suggests that a proteolytically processed, enzymatically inactive form of CsgA that is anchored to the outer membrane serves as the actual C signal through direct cell contact. Perhaps both activities figure into CsgA function. Regardless, CsgA is one of the most important proteins during fruiting body formation, and much like Spo0A in *B. subtilis* sporulation, is able to induce different processes at different levels of expression. Low levels of CsgA induce a response known as “rippling”, where *M. xanthus* swarms appear to be rippled like the surface of disturbed water. Rippling is caused by a change in motile behavior and likely functions in scavenging nutrients from dead cells. Intermediate CsgA levels induce aggregation of cells into mounds, and high CsgA levels induce sporulation. CsgA levels are known to rise steadily during fruiting body formation, and exogenously supplying CsgA at high levels causes *M. xanthus* to turn into spores before aggregation has occurred. Thus, regulated accumulation of CsgA is necessary for the proper timing of events during fruiting body formation. While the exact nature and sensing mechanism of the C signal is not known, C signaling is needed for phosphorylation of FruA, an orphan response regulator with a DNA binding domain. Strains lacking FruA cannot ripple, aggregate, or sporulate, though how FruA specifically impacts these processes is not clear. *M. xanthus* fruiting body formation is a wonderful model to study fundamental principles of multicellularity, and spatial and temporal regulation are critical to the process.

Spore Formation of *Streptomyces coelicolor*

Streptomyces coelicolor is a member of the Actinobacteria, and more specifically of the Actinomycetes. While perhaps best known as a major source of clinical antibiotics and other beneficial secondary metabolites, the Actinomycetes are a group of bacteria that share many characteristics in common with fungi. They are principally soil-dwelling, and grow in long, filamentous, branching cells called “hyphae” in the soil subsurface, with the total subsurface hyphal mat referred to as a “mycelium”. Under nutrient limitation, “aerial hyphae” are produced that grow vertically and exit the substrate. The ends of aerial hyphae then develop into chains of spores.

Whether growing in the soil or in a laboratory agar medium, the mycelium grows in an aqueous environment. When aerial hyphae are produced, they must exit the aqueous environment. To do so, they must pass through the air-liquid interface, which presents a significant physical barrier. So potent is this barrier that *S. coelicolor* has two semi-redundant systems to penetrate the air-liquid interface, and mutants defective in these systems are unable to produce aerial hyphae. The first system is the production of an oligopeptide SapB. SapB is a lantibiotic, which are ribosomally synthesized oligopeptide antibiotics. SapB is made by the *ramCSAB* cluster of genes, where *ramS* encodes the SapB oligopeptide, *RamC* processes and matures the oligopeptide into the finished form, and *RamAB* form an ABC transporter for extracellular export. SapB has no demonstrated antibiotic activity and instead appears to be a surfactant, which serves to reduce surface tension at the air-liquid interface, making it easier for aerial hyphae to break that barrier. The *ramCSAB* cluster is regulated by the *RamR* response regulator, but how *RamR* is regulated is unknown. The second system for penetrating the air-liquid interface is the production of the “chaplin” proteins. The *S. coelicolor* chaplins are an unusual family of 8 proteins with conserved hydrophobic domains. These proteins are exported and anchored to the exterior of aerial hyphae, forming a hydrophobic sheath around the cell. Filaments of chaplins are organized into a beautiful basket-like network of filaments by proteins called “rodmins” (Fig. 6). This hydrophobic sheath allows the cell to exit the aqueous environment, and may also protect aerial hyphae against desiccation while in the air. A number of “bald” mutants have been found, so-called because they do not produce the fuzzy aerial hyphae and the colonies appear smooth, yet all of these mutations seem to culminate in SapB/chaplin production because overexpression of *RamR* leads to SapB and aerial hyphae formation in all bald mutants. Many bald mutations are in predicted transcription factors, and some extracellular signaling function may be involved, but how all these factors link together is still unknown.

Fig. 6 Electron micrograph of basket-like networks of chaplin filaments on the surface of *Streptomyces* spores. Modified from Di Berardo, C., Capstick, D.S., Bibb, M.J., *et al.*, 2008. Fig. 7 Morphogenesis of *S. coelicolor* aerial hyphae into spores. Modified from Flärdh, K., Buttner, M.J., 2009. *Streptomyces* morphogenetics: Dissecting differentiation in a filamentous bacterium. *Nat. Rev. Microbiol.* 7, 36–49. Copyright 2009 Macmillan Publishers Limited.

As aerial hyphae grow, they become tipped with a long, non-septated compartment that has been referred to as a “sporogenic cell” (Fig. 7). Inside this cell, the *S. coelicolor* chromosome is extensively replicated, resulting in often more than 50 copies. Genome copies then become evenly spaced throughout the sporogenic cell. This is then followed by multiple, synchronous cell divisions between spaced chromosomes, producing individual spore compartments, each with a copy of the chromosome, which are then matured into full spores. The cell division events that produce spore compartments represents a massive switch in the growth/cell wall synthesis pattern of the organism. Most rod-shaped cells that divide by binary fission grow by adding peptidoglycan along the full lateral length of the cell wall, then divide by directing peptidoglycan synthesis inward at the midcell. Growth of *S. coelicolor* is very different. Vegetative hyphae grow by a process of tip extension, where new peptidoglycan synthesis occurs only at the tips of hyphal branches (a process mediated by the DivIVA protein), and cells are infrequently septated. One of the major proteins responsible for septum formation, FtsZ, is essential in almost every bacterium but not in *S. coelicolor*. However, FtsZ is necessary for spore formation. FtsZ forms a helical filament along the length of the sporogenic cell and is then separated out in a series of evenly spaced rings. How these rings achieve even spacing is not clear, but probably involves the ParAB chromosome partitioning system. The FtsZ rings direct peptidoglycan synthesis inward, creating septa and thus spore compartments. A thick peptidoglycan layer is produced around each compartment (mediated by the bacterial actin homolog MreB), with a coincident change in spore compartment shape from cylindrical to ovoid. A number of mutants have been found that produce aerial hyphae but cannot complete sporulation. As a result, the colonies do not produce a gray spore pigment and instead remain white in color, leading to these mutants being referred to as “white mutants”. Like the bald mutants, a number of white mutations have been identified in predicted transcription factors, but if/how they are organized into regulatory networks is not clear. Nor is the interplay between bald and white systems well characterized. Clearly the regulatory systems of *S. coelicolor* require further investigation.

Heterocyst Formation in *Anabaena*

Anabaena sp. strain PCC 7120 is a member of the Cyanobacteria, which are Gram negative bacteria that perform oxygenic photosynthesis and are major players in the global cycling of carbon, nitrogen, and oxygen. Some groups of cyanobacteria (including *Anabaena*) grow in a filamentous fashion, where each cell division occurs along the same axis, leading to chains that

Fig. 8 Morphological differentiation of *Anabaena*. (A) *Anabaena* filament grown with excess combined nitrogen. (B) *Anabaena* filament after 24 h combined nitrogen starvation. Arrows indicate heterocysts. Modified from Zhang, C., Laurent, S., Sakr, S., Peng, L., Bédu, S., 2006. Heterocyst differentiation and pattern formation in cyanobacteria: A chorus of signals. *Mol. Microbiol.* 59 (2), 367–375. Copyright 2005 Blackwell Publishing Ltd.

can be hundreds of cells long. However, the outer membrane is not included in the cell division process, so the filament of cells has one continuous outer membrane which results in a single, shared periplasmic space. Additionally, the cytoplasm of adjacent cells are connected by tiny channels called microplasmodesmata, which may be proteinaceous tubes formed of SepJ (FraG) protein. When grown in the presence nitrate or ammonia, the chain of cells appears uniform. However, when these nitrogen sources are depleted, some cells in the filament will differentiate into a specialized cell type called a “heterocyst” (Fig. 8). Heterocysts are terminally differentiated cells specializing in fixing atmospheric N_2 into bioavailable nitrogen.

Fixing nitrogen poses a mechanistic problem for cyanobacteria. These bacteria use Photosystem II during photosynthesis, so O_2 is given off as a waste product. However, O_2 permanently inactivates the nitrogenase enzymes that fix nitrogen. To solve this problem, heterocysts undergo several physiological changes to protect the cell from O_2 contamination. First, Photosystem II in heterocysts is degraded. Second, thick glycolipid and exopolysaccharide layers are added to the cell to limit exogenous O_2 from diffusing in. Lastly, the shape of the heterocyst cytoplasm is altered to minimize the junction area with adjacent cells, likely to minimize diffusion of O_2 generated by adjacent cells into the heterocyst. All these processes serve to create a micro-oxic environment inside heterocysts conducive to nitrogen fixation. Vegetative cells perform photosynthesis and provide carbon and reductants (principally in the form of sucrose) to the heterocyst, while the heterocyst provides nitrogen compounds to the vegetative cells. Clearly molecular sharing between cells is critical, and it is likely microplasmodesmata aid this function.

Amination of the TCA cycle intermediate α -ketoglutarate to glutamate is the main nitrogen assimilation mechanism in bacteria. Heterocyst formation begins with the sensing of “combined nitrogen” (i.e., nitrate and/or ammonia) depletion by the build-up of α -ketoglutarate. α -ketoglutarate binds to the transcriptional regulator NtcA, increasing its affinity for DNA. Activated NtcA induces expression of the response regulator NrrA, which then induces expression of the master regulator of heterocyst development HetR. HetR is a serine protease that also has DNA binding activity. By 3.5 h after depletion, *hetR* expression is seen in a pattern of cells resembling those that will become heterocysts, and mutants of *hetR* arrest heterocyst formation at early stages.

The pattern of heterocyst formation in cyanobacterial chains is particularly fascinating. Heterocysts arise within chains with almost mechanical regularity; one heterocyst every ten-to-twenty vegetative cells. As the cells in the chain grow and divide, new heterocysts arise to maintain this pattern. Presumably this maximizes the efficiency of molecular exchange between heterocyst and vegetative cells and does not wastefully commit cells to a terminal process that could otherwise remain viable. The major mechanism of determining heterocyst pattern formation is centered around the product of the *patS* gene and is consistent with a longstanding model wherein heterocyst cells produce an inhibitor of heterocyst formation that diffuses into the cell chain in a gradient, thus preventing cells adjacent to a heterocyst from differentiating. All heterocyst producing cyanobacteria have a *patS* gene, encoding proteins varying in length from 13 to 90 amino acids, but all end with the amino acid sequence RGSGR. Proteolytic processing and release of the carboxyl terminus as a pentapeptide is thought to be the diffusible inhibitor. A *patS* null mutant produces many heterocysts, often adjacent to each other, while *patS* overexpression completely inhibits heterocyst formation. Exogenous addition of synthetically made pentapeptide also completely inhibits heterocyst formation. Proper heterocyst patterning can be achieved in a *patS* mutant by expressing *patS* from a different heterocyst-dependent promoter. However, expressing just the pentapeptide from that same promoter does not restore the pattern, suggesting there are other facets to this system. The *patS* pentapeptide has been shown to inhibit HetR’s ability to bind DNA in a very specific manner, suggesting that pattern formation of heterocysts is accomplished by specifically inhibiting HetR in heterocyst-adjacent cells. There also may be other unknown regulatory

factors participating in heterocyst pattern formation. *Anabaena* and other filamentous cyanobacteria are tremendous systems to study how biological processes create patterns, which is an important concept in biology from the molecular level all the way up to ecosystems.

Bacterial Flagella[☆]

Structure

Filament

The flagellum is a complex structure composed of many different kinds of proteins. However, the term flagellum often indicates the flagellar filament only since the filament is the major portion of the entire flagellum. Especially, in earlier papers, the term flagella always denoted filaments. In this section, I am going to describe the filament and may occasionally call the filament flagellum.

Number of Flagella Per Cell

The number and location of flagella on a cell is one of the readily discernible traits for the classification of bacterial species. The number ranges from one to several hundreds depending on the species, and hence the nomenclature: monotrichous (one) or multitrichous (two or more). Occasionally, the term “amphitrichous” is used for two flagella.

There are three possible locations on a cell body for flagella to grow: polar (at the axial ends of the cell body), lateral (at the middle of the cell body), or peritrichous (anywhere around the cell body). In some cases, “lateral” is used as the counterpart of “polar,” as in the two flagellar systems of *Vibrio alginolyticus*: polar sheathed flagellum and lateral plain flagella. The “lateral” flagella have been sometimes mistaken as “peritrichous” flagella, but now there are a several lines of evidence that these two are different from each other: (1) they belong to different flagellar families (see “Three Flagellar Families” section); (2) the gene organization of the two is different (see “Flagellar Genes” section); and (3) lateral flagella are inducible in higher viscosity environments, but peritrichous flagella are not. Thus, lateral flagella seem to have their own mechanism for localization on the cell.

A tuft of flagella growing from a pole is called lophotrichous. In most cases, flagella can be named by a combination of number and location; for example, the polar lophotrichous flagella of *Spirillum volutans*.

Although ordinary flagella are exposed to the medium, some flagella are wrapped with a sheath derived from the outer membrane (e.g., *Vibrio cholerae*, *Helicobacter pylori*). In an extreme case such as spirochaetes, flagella are confined in a narrow space between the outer membrane and the cell membrane and thus are called the periplasmic flagella or axial filaments. The flagella still can rotate; the helical cell body works as a screw, and the flagella counterbalance the torque on the cell body.

Filament Shape and Polymorphic Transition (Fig. 1)

Filament shape is helical. In theory, there are two types of helices, right-handed and left-handed; for example, *Salmonella* spp. have a left-handed filament and *Caulobacter crescentus* has a right-handed filament under physiological conditions. However, it should be noted that shapes of these two helices are not mirror images of each other.

Fig. 1 Helical forms of flagellar filaments. Helices are seen from a position slightly off its axial direction so that the handedness can be easily visualized. The figure shows five typical forms with their helical parameters (p : pitch, d : diameter). (a) Normal (p : 2.55 mm, d : 0.6 mm), (b) Coiled (p : 0, d : 1.0 mm), (c) Semicoiled (p : 1.26 mm, d : 0.5 mm), (d) Curly (p : 1.20 mm, d : 0.2 mm), and (e) Straight filament (p : 1, d : 0).

This article is an update of Shin-Ichi Aizawa, Bacterial Flagella[☆], Reference Module in Biomedical Sciences, Elsevier, 2014

There are several detailed filament shapes, and it will be convenient to use the names of typical shapes found in *Salmonella* spp.: Normal (left-handed), Curly (right-handed), Coiled (left-handed), Semicoiled (right-handed), and Straight. Note that we often indicate the names of filament shapes by adjectives starting with capital letters. The helical parameters of these helices are discrete and distinguishable from one another.

Flagella can switch between a set of helical shapes under appropriate conditions; not only helical pitch but also helical handedness is interchangeable. The transformation of shapes can be induced by physical or chemical perturbation (torque, temperature, pH, salt concentration of medium, etc.). Genetic changes such as point mutations in the flagellin (the component protein of the flagellar filament) gene also result in transformation of helices, but some mutant flagella such as straight flagella have no freedom to transform into another helix.

This phenomenon called “polymorphism” of flagella is a visible example of conformational changes in proteins and, therefore, has evoked an idea of a functional role in motility; could polymorphism of the flagellum by itself cause the motion? The answer is No. Flagella are passive in terms of force generation. Polymorphism of flagella is observed to occur naturally on actively motile cells with peritrichous flagella. The helical transformation is necessary for untangling a jammed bundle of tangled flagella.

When Normal flagella in a jammed bundle are transformed into Curly flagella, knots of tangled flagella run toward the free end of each flagellum to untangle the jammed bundle.

Models that explain the polymorphism were first introduced by Sho Asakura in 1970 and theoretically strengthened by Chris R. Calladine in 1978. Twisting and bending a cylindrical rod give rise to a helix. Models predict 12 shapes, and 8 of them have been found in existing filaments: Straight with a left-handed twist, f1, Normal, Coiled, Semicoiled, Curly I, Curly II, and Straight with a right-handed twist. Only a small energy barrier seems to lie between two neighboring shapes. Polymorphic transition occurs from one shape to its neighbors; for example, in a transition from Normal to Curly I, the filament briefly takes on Coiled and Semicoiled forms.

Three Flagellar Families (Figs. 2 and 3)

The bacterial flagellum transforms its typical shape into several distinguishable helical shapes (polymorphs) under various environmental conditions as mentioned above. Therefore, we have regarded flagella from other species as one of those polymorphs

Fig. 2 Flagellar family. According to the helical parameters, flagella are divided into three families: Family I for peritrichous flagella, Family II for polar flagella, and Family III for lateral flagella.

Fig. 3 The pitch-diameter ($p-\pi d$) plot. In the $p-\pi d$ plot, a set of polymorphs of one type of flagella is placed on a circle. The handedness was expressed as + (for right handed) or - (for left handed) of the pitch value. Polymorphs of *Salmonella* flagellum stay on a circle (thick circle) in the $p-\pi d$ plot: Normal, Coiled, and Curly II are shown (X). Polymorphs of some other species which have peritrichous flagella also stay on the same circle and thus belong to Family I (F1). Family II (F2, dotted circle) and Family III (F3, thin circle) show smaller circles in the $p-\pi d$ plot.

defined for *Salmonella typhimurium*. In 2005, we found that the polar flagellum of *Idiomarina loihiensis* appeared “Curly with left-handed helix,” which urged us to reexamine all flagella shapes known by then. Indeed, it turned out that polymorphs of polar flagella form a family distinguished from those of peritrichous flagella. A helix is uniquely defined by three parameters: the pitch (p), the helix diameter (d), and the handedness. If the handedness was expressed as $+$ (right handed) or $-$ (left handed) of the pitch value, any helices will be plotted on the pitch–diameter (p – πd) plane. For example, the parameters of the Normal filament are written as $(-2.55, 1.88)$ and those of the Curly filament as $(+1.20, 0.63)$.

Note that πd is better than d ; if a tube was flattened, a unique d disappears but πd (periphery) remains constant. Polymorphs of the *Salmonella* flagellum stay on a circle in the pitch–diameter (p – πd) plot (Fig. 3), indicating that they all belong to one family (Family I) predicted by the Calladine model. The flagellar polymorphs of *I. loihiensis* (Family II) are smaller than those of Family I. Precisely to say, the pitch and diameter of Family II flagella are half of the same of Family I flagella. Furthermore, lateral flagella had helical parameters much smaller than those of the two families and thus belonged to a new family (Family III).

Flagellin

The component protein of the filament is called flagellin. Although the flagellum of many bacteria is composed of one kind of flagellin, some flagella consist of more than two kinds of closely related subspecies of flagellin. The molecular size of flagellin ranges from 20 to 60 kDa. Enterobacteria tend to have larger molecules, while species living in fresh water have smaller molecules.

The three-dimensional structure of the flagellin in the filament of *S. typhimurium* has been solved at the atomic level.

One of the most characteristic features of flagellin is evident even in the primary structure of the molecule; the amino acid sequences of both terminal regions are well conserved, whereas that of the central region is highly variable even among species or subspecies of the same genera. As a matter of fact, this hypervariability of the central region gives rise to hundreds of serotypes of *Salmonella* spp.

The terminal regions are essential for binding of each molecule to another to polymerize into a filament. Complete folding of flagellin occurs during assembly; although the terminal regions do not take on any specific secondary structure in solution, they are converted into an α -helix upon polymerization.
